## Section 1 General Basic and Clinical Considerations

1 The History and Physical Examination

- The History
- The Physical Examination

Common Signs and Symptoms of Chest Disease in Children
Conclusion
Suggested Reading

## 2 Molecular Determinants of Lung Morphogenesis

Introduction
Organogenesis of the Lung
Molecular Mechanisms Directing Lung Development
Development of the Pulmonary Host Defense Systems
Gene Mutations in Lung Development and Function
Summary
References

## 3 Basic Genetics and Epigenetics of Childhood Lung Disease

Types of Genetic Variation
Technologies to Identify Genetic Variation
Interpretation of Genetic Variation
When to Consider Clinical Genetic Testing
Research Study Designs to Attribute Genetic Variation to Disease
Epigenetics—Terminology and Technology
“Multi-Omics” Approaches to Refine Genotype-Phenotype Associations
Websites
References

## 4 Environmental Contributions to Respiratory Disease in Children

Vulnerability of Children to Adverse Environmental Exposures

Environmental Contributions to Acute Respiratory Illness and Pneumonia

Environmental Contributions to Asthma

Summary

References

## 5 The Surfactant System

Surfactant Composition and Metabolism

Surfactant Metabolism and Secretion

Alveolar Life Cycle of Surfactant

Surfactant Function

Pressure-Volume Curves

Host Defense Functions of Surfactant

Surfactant Deficiency

Surfactant Treatment of Surfactant Deficiency

References

## 6 The Structural and Physiologic Basis of Respiratory Disease

Normal Lung Anatomy and Cell Function

Airways

Alveolar Region

Pulmonary Vascular System

Lymphatic System

Innervation of the Lung

Interstitium

Growth and Development of the Lung

The Lung at Birth

Postnatal Lung Growth

Ventilation and Mechanics of Breathing

Definitions and Symbols

Elastic Recoil of the Lung

Compliance of the Lung

Elastic Properties of the Chest Wall

Lung Volumes

Regional Lung Volumes

Dynamic (Flow-Resistive) Properties of the Lung

Distribution of Ventilation

Pulmonary Circulation

Pulmonary Vascular Pressures

Pulmonary Vascular Resistance

Distribution of Blood Flow

Methods of Evaluating the Pulmonary Circulation

Muscles of Respiration

Gas Exchange

Alveolar Ventilation

Dead Space

Diffusion

Shunt and Ventilation-Perfusion Relationships

Systemic Gas Transport

Oxygen Therapy

Carbon Dioxide Transport and Acid-Base Balance

Tissue Respiration

Regulation of Respiration

Sensory Feedback System

Metabolic Functions of the Lung

References

7 Biology and Assessment of Airway Inflammation

Introduction

Allergic Inflammation

Acute Inflammation

Chronic Inflammation

Inflammatory Cells

Structural Cells as Sources of Mediators

Inflammatory Mediators

Neural Mechanisms

Transcription Factors

Antiinflammatory Mechanisms

Direct Measurements of Airway Inflammation

Noninvasive Assessment of Airway Inflammation

Is AHR an Inflammatory Surrogate?

Other Potential Indirect Inflammatory Markers

Is There a Role for Assessing Inflammation in Pediatric Respiratory Disease?

Therapeutic Implications

Conclusion

References

## 8 Lung Defenses

Intrinsic Lung Defenses

Innate Lung Defenses

Adaptive Lung Defenses

Role of Programmed Cell Death and “Clearing the Garbage” in Lung Homeostasis

Summary

References

## 9 Bronchoscopy and Bronchoalveolar Lavage in Pediatric Patients

Instrumentation

Techniques for Bronchoscopy

Anesthesia for Bronchoscopy

Indications for Diagnostic Bronchoscopy

Contraindications to Bronchoscopy

Bronchoalveolar Lavage

Diagnostic Techniques Other Than Bronchoalveolar Lavage

Therapeutic Bronchoscopy

Complications of Bronchoscopy

Economic Aspects of Bronchoscopy

References

## 10 Diagnostic Imaging of the Respiratory Tract

Plain Radiography

Specific Features of the Chest Radiograph in Children

Systematic Review of the Chest Radiograph

Fluoroscopic Techniques

Computed Tomography

Isotropic Computed Tomography

Data Processing

Review of Findings

Pitfalls

Radiation Dose

High-Resolution Computed Tomography

Controlled Ventilation Technique

Interpretation

Angiography

Magnetic Resonance Imaging

Endobronchial Ultrasonography

Ultrasonography

Radionuclide Imaging

Conclusion

References

## 11 Pulmonary Function Tests in Infants and Children

Introduction

Measurement of Lung Volumes

Measurement of Diffusing Capacity of Carbon Monoxide

Measurement of Forced Expiration

Measurement of Resistance and Compliance

Measurement of Gas Mixing

References

12 Exercise and Lung Function in Child Health and Disease

The Biological Importance of Physical Activity in the Growing Child

From the Playground to the Bench to the Physician's Office

Physiologic Response to Progressive Exercise Testing

The Challenge of Scaling Cardiopulmonary Exercise Testing to Body Mass in Children and Adolescents and the Special Case of Obesity

Development of Physiological Responses to Exercise in Children and Adolescents and Predicting Cardiopulmonary Health Across the Lifespan

Searching for Normal Values in Pediatric Cardiopulmonary Exercise Testing

Asthma and Exercise

Physical Activity, Exercise and Cystic Fibrosis

Physical Activity, Exercise, and Lung Disease of Prematurity

Exercise at Altitude in Child Health

High Altitude and Children With Chronic Lung Disease

Exercise and Laryngeal Obstruction

Toward the Future: Exercise in the Age of Omics

References

13 Integrating Patient-Reported Outcomes Into Research and Clinical Practice

Definition of a Patient-Reported Outcome

Development and Utilization of Patient-Reported Outcomes

Health-Related Quality of Life Measures

Developmental Considerations

Use of Proxy-Respondents

Clinical Utility

Summary

Review of Disease-Specific Respiratory Health-Related Quality of Life Measures

Conclusions and Future Directions

References

14 Transition From Pediatric to Adult Care

Introduction

What Is Transition?

Why Is Transition Important?

Transition: A Practical Approach

Barriers to Transition

Summary

References

15 Long-Term Consequences of Childhood Respiratory Disease

Introduction

How the Lung Develops in Health and Disease

The End-Stage—Chronic Obstructive Pulmonary Disease

Long-Term Consequences of Specific Diseases

Summary and Conclusions

References

16 Drug Administration by Inhalation in Children

Advantages and Disadvantages of Aerosols for Drug Delivery

What Is a Therapeutic Aerosol?

Principles of Aerosol Delivery

Assessment Techniques

Aerosol Devices

Dosage Considerations

Advice and Training for Parents

Progress Toward the Ideal Delivery System

References

17 Physical Therapies in Pediatric Respiratory Disease

General Principles of Physiotherapy

Role of Physiotherapy in Pediatric Respiratory Disease

Respiratory Physiotherapy in Specific Conditions

Conditions Not Generally Amenable to Physiotherapy

Summary

References

18 Congenital Lung Disease

Introduction

Clinical Approach

The Size of the Problem: Epidemiology of Congenital Malformations of the Lung

Antenatal Diagnosis and Management of Congenital Lung Disease

Specific Diagnoses: Congenital Diaphragmatic Hernia

Specific Diagnoses: Upper Respiratory Tract Atresias

Specific Postnatal Problems: Congenital Abnormalities of the Upper Airway

Examination of a Child Presenting in the Clinic Setting

The Emergent/Marginal Airway and Difficult Intubations

Extubation Difficulties/Failed Extubation

Congenital Abnormalities of the Larynx

Vocal Cord Paralysis

Congenital Abnormalities of the Trachea

Specific Problems: Congenital Bronchial Abnormalities

Specific Problems: Parenchymal Lesions

Specific Problems: Overexpansion, Aplasia and Ectopia

Specific Problems: Abnormal Connections Between the Bronchial Tree and Other Structures

Specific Problems: Congenital Disease of the Pulmonary Arterial Tree

Specific Problems: Congenital Disease of the Pulmonary Venous Tree

Specific Problems: Abnormalities of the Connections Between the Pulmonary Arterial and Venous Trees

Specific Problems: Congenital Disease of the Lymphatic Tree

Specific Problems: Congenital Disorders of the Chest Wall

Specific Problems: Congenital Cardiac Disorders

Specific Problems: Multisystem Congenital Disorders That Affect the Lung

Role of Specific Investigations

Summary and Conclusions

References

19 Respiratory Disorders in the Newborn

Initiation of Respiration at Birth

Fetal Lung Fluid

Respiratory Depression at Birth

Delivery Room Resuscitation

Ventilatory Control

## Section 3 Pulmonary Disease in the Intensive Care Unit

---

34 Principles of Mechanical Ventilation

History

Indications for Mechanical Ventilation

Composition of a Mechanical Ventilator

Modes of Ventilation

Noninvasive Ventilation

High-Frequency Ventilation

Neurally Adjusted Ventilator Assistance

Hemodynamic Effects of Mechanical Ventilation

Mechanical Ventilation in Specific Conditions

Management During Mechanical Ventilation

Complications of Mechanical Ventilation

Conclusion

References

## 35 Childhood Pulmonary Arterial Hypertension

Introduction

Definition and Classification

Epidemiology and Etiology

Neonatal Pulmonary Hypertension

Associated Pulmonary Arterial Hypertension With Congenital Heart Disease

Management

Oxygen

Additional Pharmacotherapy: Cardiac Glycosides, Diuretics, Antiarrhythmic Therapy, Inotropic Agents, and Nitrates

Atrial Septostomy

Lung Transplantation

Conclusions

References

## 36 Pulmonary Edema

Anatomic Considerations

Factors Responsible for Fluid Movement

Mechanisms That Cause Pulmonary Edema

Clearance of Pulmonary Edema Fluid

Pathophysiologic Consequences of Edema

Clinical Presentation

Clinical Disorders Causing Pulmonary Edema

Therapy

References

37 Respiratory Complications of Intensive Care

History of Pediatric Intensive Care

Indications for Intubation and Mechanical Ventilation

Ventilation Strategies

Complications of Mechanical Ventilation

Notices
Knowledge and best practice in this field are constantly changing.

As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.
Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.
With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.
To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

# Preface

Welcome to the ninth edition of *Kendig's Disorders of the Respiratory Tract in Children,* which has gone through many changes since the last edition. First, our two senior editors, Dr. Vic Chernick and Dr. Tom Boat, have chosen to hang up their red pens, despite the best efforts of the rest of us to keep them working. A fitting tribute to either of them would take up many, many pages; suffice it to say that they have been giants in our field, and more of us than can be listed here owe them a huge debt. Retire in Peace! We all want to have it on record that the health and high qualities of this volume are in large measure owed to them, while we also acknowledge that they cannot be held responsible for the flaws of their successors.

The editorial team has expanded, and not just because Vic and Tom have left behind two huge pairs of shoes to fill. We wanted to have more global representation on the editorial team, acknowledging that globalization has changed our specialty forever. A child febrile in West Africa can be in England within hours, triggering an Ebola crisis. John Donne reminded us that no man is an island, and today, no island is isolated (even post-Brexit); we have to know about diseases from all around the world if we are to offer the care our children have the right to expect. Furthermore, we can and should learn from each other. Many techniques pioneered in the developed world are less expensive and have been exported to low- and middle-income settings. However, the low- and middle-income countries have exported valuable lessons in the other direction: the focused approach to the millennium development goals, learning from best practice, and new diseases because of new exposures. In the 21st century, learning is a two-way process. We welcome to the editorial team, joining the existing team from the United States, Canada, and Europe, Professors Heather Zar from South Africa, Peter Sly from Australia, and Albert Li from Hong Kong. We believe we have thereby made this edition truly global, with huge clinical relevance all around the world.

In addition to the changes in the editorial team, we have 87 new authors and 8 new chapters, with all the other chapters being completely revised, reorganized, and updated. Our new chapters reflect many developments in pediatric pulmonology. The era of biologicals is upon us, and we have chapters on molecular therapies for cystic fibrosis and asthma. The importance of interactions with other specialties is reflected in chapters on the principles of mechanical ventilation, respiratory complications of intensive care, and congenital heart disease, as well as pulmonary embolism (no organ is an island, either). Globalization is reflected with a chapter on emerging lung infections, and there are other new chapters on the respiratory complications of Down syndrome and other genetic disorders, as well as hypersensitivity pneumonitis and eosinophilic lung diseases. We have attempted to avoid dishing up the mixture as before, good though it was, in favor of revivifying the book.

The final revivifying theme is the transition from the paper copy of the 20th century to the multimedia and Internet resources of the 21st. There is a rich crop of online resources, in the eBook, including 50 videos, approximately 550 illustrations that can be downloaded for presentations and teaching, and extensive bibliographies with hyperlinks to the original articles.

So we hope you find this ninth edition a worthy successor to its eight forebears. We want to thank our team of authors for their hard and excellent work, and (for the most part!) meeting deadlines, or at least not going too far beyond them. Huge thanks to Elsevier and their whole editorial team, especially Lisa Barnes, for unfailing tolerance of our many sins. To you all belongs the credit for much that we believe is good, and to the editors the blame for any bad things that have slipped through. Special thanks to Bob Wilmott, who has undertaken the monumental task of oversight of the whole volume to iron out unnecessary repetitions and spot overlaps and omissions. We hope that you, the reader, gets as much from studying this book as we have from editing it. Finally, as the ink dries on the blessed words “The End,” work starts on the next edition. Please e-mail any of us to let us know what has worked and what has not, what should have been in, and what should never have been allowed to see the light of day, so we can make the 10th edition better yet.

*Andrew Bush*

on the behalf of the editors

# The History and Physical Examination

*Hans Pasterkamp MD, FRCPC, David Zielinski MD, FRCPC, FCCP*

In the 21st century, the diagnosis of disease still requires a detailed medical history and a thorough physical examination. For the majority of patients in many areas of the world, additional information from laboratory tests and other data remain rather limited. Modern science and technology have changed the situation considerably in industrialized nations, but we are paying a high price. Cost containment in health care has become essential. Physicians need to be skillful in their history taking and physical examination techniques so they can collect a maximum amount of information before ordering expensive investigations. The relevance of these skills in pediatric respiratory medicine is exemplified by clinical severity scores that are widely used in care maps for asthma, bronchiolitis, and croup, or in scores developed to manage patients suspected to have acute severe respiratory syndromes (e.g., during outbreaks of SARS, H1N1, and other forms of influenza).

The diagnosis of disease in children has to rely on the patient's history and on observations gathered during the physical examination, even more than in older patients. Young children cannot follow instructions and participate in formal physiologic testing, and physicians hesitate before subjecting their pediatric patients to invasive diagnostic procedures. Diseases of the respiratory tract are among the most common in children, and in the majority of cases they can be correctly identified from medical history data and physical findings alone. The following review of the medical history and physical examination in children with respiratory disease includes some observations that were made with the help of modern technology. These technical aids do not lessen the value of subjective perceptions, but rather emphasize how new methods may further our understanding, sharpen our senses, and thereby advance the art of medical diagnosis.

# The History

## General Principles

The medical history should be taken in an environment with comfortable seating for all, a place for clothing and belongings, and some toys for younger children. Privacy has to be assured, without the usual interruptions by phone calls and other distractions. If possible, the physician should see one child at a time because the presence of young siblings or other children in the room can be distracting. Data that should be recorded at the beginning include the patient's name and address, the parents' or guardians' home and work phone numbers, the name of the referring physician, and information on the kindergarten or school if this is relevant. In many cases, the history will be given by someone other than the patient, but the physician should still directly ask even young children about their complaints. When asking about the history of the present illness, the physician should encourage a clear and chronological narrative account. Questions should be open-ended, and at intervals the physician should give a verbal summary to confirm and clarify the information. Past medical history and system review are usually obtained by answers to direct questions.

## Structure of the Pediatric History

The physician should note the source of and the reason for referral. On occasion, the referral is made by someone other than the patient or the parents (e.g., a teacher, relative, or friend). The physician should identify the *chief complaint* and the *person most concerned about it.* The *illness at presentation* should be documented in detail regarding onset and duration, the environment and circumstances under which it developed, its manifestations and their treatments, and its impact on the patient and family. Symptoms should be defined by their qualitative and quantitative characteristics as well as by their timing, location, aggravating or alleviating factors, and associated manifestations. Relevant past medical and laboratory data should be included in the documentation of the present illness.

This general approach is also applicable when the emphasis is on a single organ system, such as the respiratory tract. The onset of disease may have been gradual (e.g., with some interstitial lung diseases) or sudden (e.g., with foreign body aspiration). The physician should ask about initial manifestations and who noticed them first. The age at first presentation is important, because respiratory diseases that manifest soon after birth are more likely to have been inherited or to be related to congenital malformations. Depending on the duration of symptoms, the illness will be classified as *acute, subacute, chronic,* or *recurrent.* These definitions are arbitrary, but diseases of less than 3 weeks' duration are generally called *acute;* diseases between 3 weeks' and 3 months' duration are *subacute;* and those that persist longer than 3 months are *chronic.* If symptoms are clearly discontinuous, with documented intervals of well-being, the disease is *recurrent.* This distinction is important because many parents may perceive their child as being chronically ill, not realizing that young normal children may have six to eight upper respiratory infections per year, particularly during the first 2 years if the child is in a daycare setting, or if he or she has older siblings.

Respiratory diseases are often affected by environmental factors. There should be a careful search for seasonal changes in symptoms to uncover possible allergic causes. Exposure to noxious inhaled agents, for example, from industrial pollution or more commonly from indoor pollution by cigarette smoke, can sustain or aggravate a patient's coughing and wheezing. Similarly, a wood-burning stove used for indoor heating may be a contributing factor. The physician should therefore obtain a detailed description of the patient's home environment. Are there household pets (e.g., dogs, cats, or hamsters) or birds (e.g., budgies, pigeons, or parrots)? What plants are in and around the house? Are there animal or vegetable fibers in the bedclothes or in the floor and window coverings (e.g., wool, feathers)? Are there systems in use for air conditioning and humidification? Is mold visible anywhere in the house?

There may be a relationship between respiratory symptoms and daily activities. Exercise is a common trigger factor for coughing and wheezing in many patients with hyperreactive airways. A walk outside in cold air may have similar effects. Diurnal variation of symptoms may be apparent, and attention should be paid to changes that occur at night. These changes may also be related to airway cooling, or they may reflect conditions that are worse in the recumbent position, such as postnasal drip or gastroesophageal reflux (GER). Food intake may bring on symptoms of respiratory distress when food is aspirated or when food allergies are present.

Many children who present with respiratory symptoms are suffering from infection, most often viral. It is important to know whether other family members or people in regular contact with the patient are also affected. When unusual infections are suspected, questions should be asked about recent travel to areas where exotic organisms may have been acquired. Drug abuse by parents or by older patients and high-risk lifestyles may lead the physician to consider the possibility of acquired immunodeficiency syndrome (AIDS).

Descriptions of respiratory disease manifestations may come from the parents or directly from an older child. Common symptoms are fever, cough and sputum production, wheezing or noisy breathing, dyspnea, and chest pain. Most of these are discussed in more detail later in the chapter.

The past medical history will provide an impression of the general health status of the child. First, the birth history should be reviewed, including prenatal, natal, and neonatal events. The physician should inquire about the course of pregnancy, particularly whether the mother and fetus suffered from infections, metabolic disorders, or exposure to noxious agents (e.g., nicotine). The duration of pregnancy, possible multiple births, and circumstances leading to the onset of labor should be noted. Difficult labor and delivery may cause respiratory problems at birth (e.g., asphyxia and meconium aspiration), and the physician should ask about birth weight and Apgar scores. The physician should carefully review the neonatal course because many events during this period may affect the patient's respiratory status in later years. Were there any signs of neonatal respiratory distress (e.g., tachypnea, retractions, and cyanosis)? Treatment with oxygen or endotracheal intubation should be recorded. Some extrathoracic disorders provide valuable clues for diagnosis, such as the presence of eczema in atopic infants or neonatal conjunctivitis in an infant with chlamydia pneumonia, particularly if there was a documented infection of the mother.

Much is learned from a detailed feeding history, which should include the amount, type, and schedule of food intake. The physician should ask whether the child was fed by breast or bottle. For the newborn and young infant, feeding is a substantial physical exercise and may lead to distress in the presence of respiratory disease, much as climbing stairs does in the older patient. The question of exercise tolerance in an infant is therefore asked by inquiring how long it takes the patient to finish a feed. The caloric intake of infants with respiratory disease is often reduced despite an increased caloric requirement to support the work of breathing. This reduced caloric intake commonly results in a failure to thrive. Older patients with chronic respiratory disease and productive cough may suffer from a continuous exposure of their taste buds to mucopurulent secretions and may quite understandably lose their appetites, but medical treatment (e.g., with certain antibiotics) may have similar effects. Patients with food hypersensitivity may react with bronchospasm or even with interstitial lung disease on exposure to the allergen (e.g., milk). Physical irritation and inflammation occur if food is aspirated into the respiratory tract. This happens frequently in patients with debilitating neurologic diseases and deficient protective reflexes of the upper airways. However, pulmonary aspiration may also occur in neurologically intact children, and their ethnic background, for example, indigenous people of North America, may suggest an increased risk. A history of cough or choking during feeding should alert the physician to the possibility of pulmonary aspiration.

The physical development of children with chronic respiratory diseases may be retarded. Malnutrition in the presence of increased caloric requirements is common, but the effects of some long-term medical treatments (e.g., steroids) should also be considered. Previous measurements of body growth should be obtained and plotted on appropriate charts. Psychosocial development may be affected if chronic lung diseases (e.g., asthma or cystic fibrosis) limit attendance and performance at school or if behavioral problems arise in children and adolescents subjected to chronic therapy. More severely affected patients may also be delayed in their sexual development.

Many diseases of the respiratory tract in children have a genetic component, either with a clear Mendelian mode of inheritance (e.g., autosomal recessive in cystic fibrosis, homozygous deficiency of $\alpha_1$-antitrypsin, X-linked recessive in chronic granulomatous disease, and autosomal dominant in familial interstitial fibrosis) or with a genetic contribution to the cause. Examples of familial aggregation of respiratory disease are chronic bronchitis and bronchiectasis or familial emphysema in patients with heterozygous $\alpha_1$-antitrypsin deficiency, in which the susceptibility of the lung to the action of irritants (e.g., cigarette smoke) is increased. A mixed influence of genetic and environmental factors exists in polygenic diseases, such as asthma or allergic rhinitis.

When inquiring about the family history, the physician should review at least two generations on either side. The parents should be asked whether they are related by blood, and information should be obtained about any childhood deaths in the family. The health of the patient's siblings and also of brothers and sisters of both parents should be documented. Particular attention should be paid to histories of asthma, allergies and hay fever, chronic bronchitis, emphysema, tuberculosis, cystic fibrosis, male infertility, and sudden unexpected infant death.

The physician should obtain a detailed report of prior tests and immunizations. Quite often this requires communication with other health care providers. Results of screening examinations (e.g., tuberculin and other skin tests, chest radiographs, and Cystic Fibrosis newborn screening) should be noted. Similarly, childhood illnesses, immunizations, and possible adverse immunization reactions should be documented. If the history is positive for allergic reactions, these have to be confirmed and defined. Previous hospital admissions and their indications should be listed, and the patient's current medications and their efficacy should be documented. If possible, the drug containers and prescriptions should be reviewed. The physician may use the opportunity to discuss the pharmacologic information and the technique of drug administration, particularly with inhaled bronchodilator medications.

One of the most important goals in taking a history is to become more aware of the particular psychological and social situation of the patient. It is impossible to judge current complaints or responses to medical interventions without an individual frame of reference for each patient. The physician should encourage the child and the parents to describe a typical day at home, daycare, kindergarten, or school. This will provide valuable information about the impact of the illness on daily routines, the financial implications, the existing or absent social support structures, and the coping strategies of the family. Compliance with medical treatment is rarely better than 50%, and physicians are generally unable to predict how well their patients follow and adhere to therapeutic regimens. Compliance can improve if the patient and the parents gain a better understanding of the disease and its treatment. It is important to recognize prior experiences that the family may have had with the health care system and to understand individual spiritual, religious, and health beliefs. Particularly in children with chronic respiratory ailments whose symptoms are not being controlled or prevented, the effort and unpleasantness (e.g., of chest physiotherapy) may limit the use of such interventions. The physician should also consider the social stigma associated with visible therapy, especially among peers of the adolescent patient.

A review of organ systems is usually the last part of the history and may actually be completed during the physical examination. Although the emphasis is on the respiratory system, questions about the general status of the child will be about appetite, sleep, level of activity, and prevailing mood. Important findings in the region of the head and neck are nasal obstruction and discharge, ear or sinus infection, conjunctival irritation, sore throat, and swallowing difficulty. The respiratory manifestations of coughing, noisy breathing, wheezing, and cyanosis are discussed in detail at the end of this chapter. Cardiovascular findings may include palpitations and dysrhythmia in hypoxic patients; there may be edema formation and peripheral swelling with cor pulmonale. Effects of respiratory disease on the gastrointestinal tract may appear with cough-induced vomiting and abdominal pain. There may be a direct involvement with diarrhea, cramps, and fatty stools in patients with cystic fibrosis. The physician should ask about hematuria and about skin manifestations, such as eczema or rashes, and about swellings and pain of lymph nodes or joints. Finally, neurologic symptoms (e.g., headache, lightheadedness, or paresthesiae) may be related to respiratory disease and cough paroxysms or hyperventilation.

## The Physical Examination

Traditionally, the physical examination is divided into inspection, palpation, percussion, and auscultation. The sequence of these steps may be varied depending on the circumstances, particularly in the assessment of the respiratory tract in children. The classic components of the physical examination and some modern aids and additions are discussed in the following sections.

### Inspection

Much can be learned from simple observation, particularly during those precious moments of sleep in the young infant or toddler, who when awake can be a challenge even for the skilled examiner. First, the pattern of breathing should be observed. This includes the respiratory rate, rhythm, and effort. The respiratory rate decreases with age and shows its greatest variability in newborns and young infants (Fig. 1.1A). Reference values in hospitalized children, excluding those with respiratory disease, show higher values (see Fig. 1.1B).

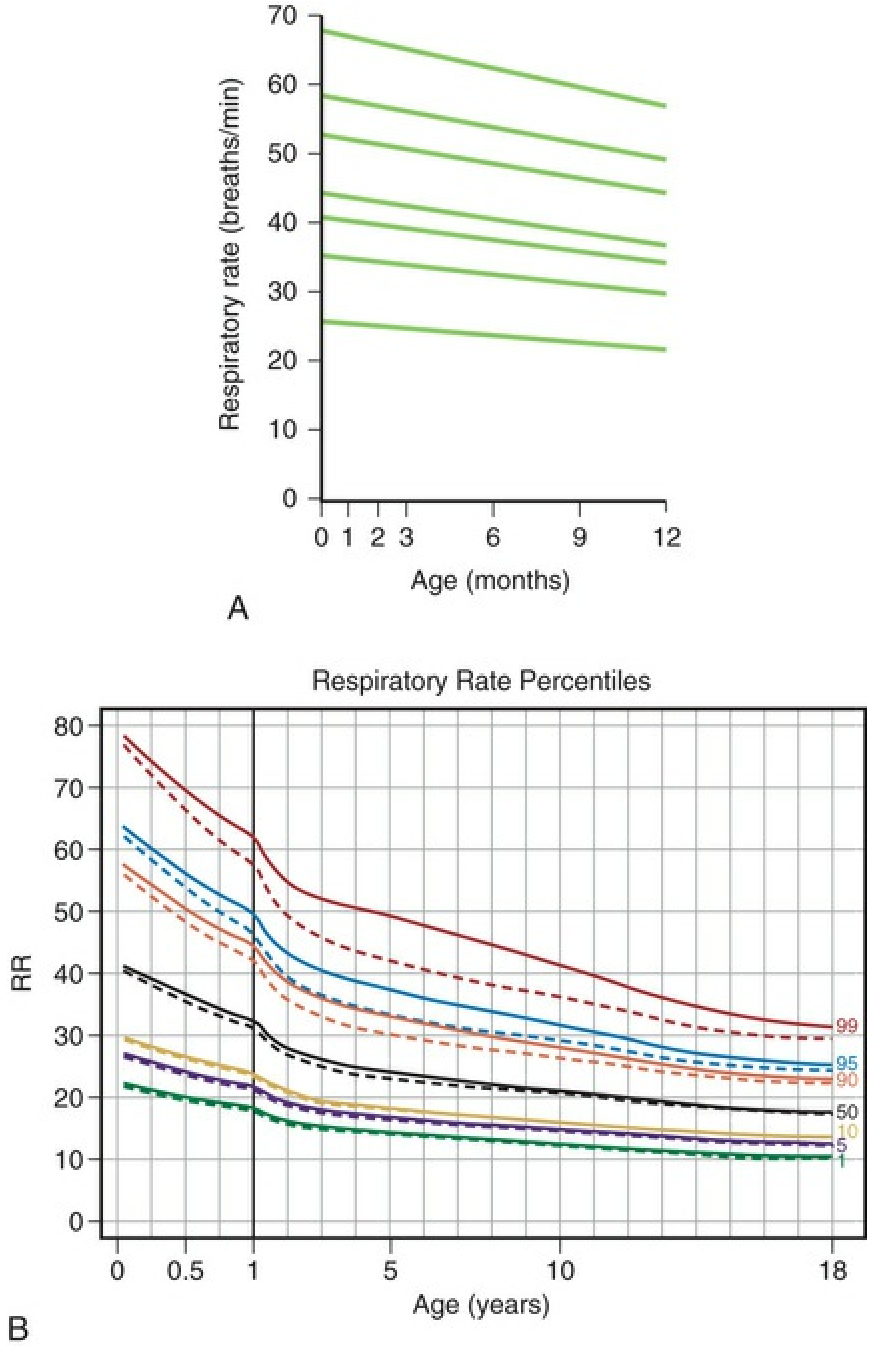

**FIG. 1.1** (A) Median and percentile curves for respiratory rates. (B) *Dotted lines* represent sensitivity analysis excluding diseases of the respiratory system. The solid vertical line at 1 year of age represents a change in scale of the x-axis. *RR,* Respiratory rate. ([A] Data from Rusconi F, Castagneto M, Gagliardi L, et al. Reference values for respiratory rate in the first 3 years of life. *Pediatrics*. 1994;94:350. [B] Data from Bonafide CP, Brady PW, Keren R, et al. Development of heart and respiratory rate percentile curves for hospitalized children. *Pediatrics*. 2013;131:e1150.)

The respiratory rate should be counted over at least 1 minute, ideally several times for the calculation of average values. Because respiratory rates differ among sleep states and become even more variable during wakefulness, a note should be made describing the behavioral state of the patient. Observing abdominal movements or listening to breath sounds with the stethoscope placed before the mouth and nose may help in counting respirations in patients with very shallow thoracic excursions.

Longitudinal documentation of the respiratory rate during rest or sleep is important for the follow-up of patients with chronic lung diseases, even more so for those too young for standard pulmonary function tests. Abnormally high breathing frequencies or *tachypnea* can be seen in patients with decreased compliance of the respiratory system and in those with metabolic acidosis. Other causes of tachypnea are fever (~5–7 breaths/min increase per degree above 37°C), anemia, exertion, intoxication (salicylates), anxiety, and psychogenic hyperventilation. The opposite, an abnormally slow respiratory rate or *bradypnea,* can occur in patients with metabolic alkalosis or central nervous system depression. The terms *hyperpnea* and *hypopnea* refer to abnormally deep or shallow respirations. At given respiratory rates, this determination is a subjective clinical judgment and is not easily quantified unless the pattern is obvious, such as the Kussmaul type of breathing in patients with diabetic ketoacidosis.

Significant changes in the rhythm of breathing occur during the first months of life. Respiratory pauses of less than 6 seconds are common in infants younger than 3 months of age. If these pauses occur in groups of three or more that are separated by less than 20 seconds of respiration, the pattern is referred to as *periodic breathing.* This pattern is very common in premature infants after the first days of life and may persist until 44 weeks postconceptional age. In full-term infants, periodic breathing is usually observed between 1 week and 2 months of age and is normally absent by 6 months of age. Apnea with cessation of air flow lasting more than 15 seconds is uncommon and may be accompanied by bradycardia and cyanosis. In preterm infants, a drop in oxygen saturation may be seen up to 7 seconds after a respiratory pause when in room air and up to 9 seconds later when on supplemental oxygen.

Other abnormal patterns include *Cheyne-Stokes breathing,* which occurs as cycles of increasing and decreasing tidal volumes separated by apnea (e.g., in children with congestive heart failure or increased intracranial pressure). *Biot breathing* consists of irregular cycles of respiration at variable tidal volumes interrupted by apnea and is an ominous finding in patients with severe brain damage.

After noting the rate and rhythm of breathing, the physician should look for signs of increased respiratory effort. The older child will be able to communicate the subjective experience of difficult breathing, or *dyspnea.* Objective signs that reflect distressed breathing are chest wall retractions, visible use of accessory muscles and the alae nasi, orthopnea, and paradoxical respiratory movements. The more negative intrapleural pressure during inspiration against a high airway resistance leads to retraction of the pliable portions of the chest wall, including the intercostal and subcostal tissues and the supraclavicular and suprasternal fossae. Conversely, bulging of intercostal spaces may be seen when pleural pressure becomes greatly positive during a maximally forced expiration. Retractions are more easily visible in the newborn infant, in whom intercostal tissues are thinner and more compliant than in the older child.

Visible contraction of the sternocleidomastoid muscles and indrawing of supraclavicular fossae during inspiration are among the most reliable clinical signs of airway obstruction. In young infants, these muscular contractions may lead to head bobbing, which is best observed when the child rests with the head supported slightly at the suboccipital area. If no other signs of respiratory distress are present in an infant with head bobbing, however, central nervous system disorders, such as third ventricular cysts with hydrocephalus, should be considered. Older patients with chronic airway obstruction and extensive use of accessory muscles may appear to have a short neck because of hunched shoulders. *Orthopnea* exists when the patient is unable to tolerate a recumbent position, for example, with severely increased upper airway resistance and obstruction during sleep.

Flaring of the alae nasi is a sensitive sign of respiratory distress and may be present when inspiration is abnormally short (e.g., under conditions of chest pain). Nasal flaring enlarges the anterior nasal passages and reduces upper and total airway resistance. It may also help to stabilize the upper airways by preventing large negative pharyngeal pressures during inspiration.

The normal movement of chest and abdominal walls is directed outward during inspiration. Inward motion of the chest wall during inspiration is called *paradoxical breathing*. This is seen when the thoracic cage loses its stability and becomes distorted by the action of the diaphragm. Classically, paradoxical breathing with a seesaw type of thoracoabdominal motion is seen in patients with paralysis of the intercostal muscles, but it is also commonly seen in premature and newborn infants who have a very compliant rib cage. Inspiratory indrawing of the lateral chest is known as *Hoover sign* and can be observed in patients with obstructive airway disease. Paradoxical breathing also occurs during sleep in patients with upper airway obstruction. The development of paradoxical breathing in an awake, nonparalyzed patient beyond the newborn period usually indicates respiratory muscle fatigue and impending respiratory failure.

Following inspection of the breathing pattern, the examiner should pay attention to the symmetry of respiratory chest excursions. Unilateral diseases affecting lungs, pleura, chest wall, or diaphragm may all result in asymmetric breathing movements. Trauma to the rib cage may cause fractures and a “flail chest” that shows local paradoxical movement. Pain during respiration usually leads to “splinting” with flexion of the trunk toward and decreased respiratory movements of the affected side. The signs of hemidiaphragmatic paralysis may be subtle. In complete unilateral paralysis, there may be a shift in the epigastric abdominal wall during deep inspiration diagonally toward the side of the lesion and upward. This may be more noticeable in the lateral decubitus position with the paralyzed diaphragm placed up, a position that tends to accentuate a paradoxical inward epigastric motion on the affected side.

Other methods to augment inspection of chest wall motion use optical markers. In practice, this technique is done by placing both hands on either side of the patient's lateral rib cage with the thumbs along the costal margins. Divergence of the thumbs during expansion of the thorax supposedly aids in the visual perception of the range and symmetry of respiratory movements. This technique is of little use in children. A more accurate method of documenting the vectors of movement at different sites (but one that is not yet practical for bedside evaluation) is to place a grid of optical markers on the chest surface and film their positional changes during respiration relative to a steady reference frame. A similar concept is used in optical studies of chest deformities. Projection of raster lines onto the anterior chest surface allows stereographic measurement of deformities, such as pectus excavatum, and augments the visual image of the surface shape (Fig. 1.2). In practice and without such tools, however, the physician should inspect the chest at different angles of illumination to enhance the visual perception of chest wall deformities. Their location, size, symmetry, and change with respiratory or cardiac movements should be noted.

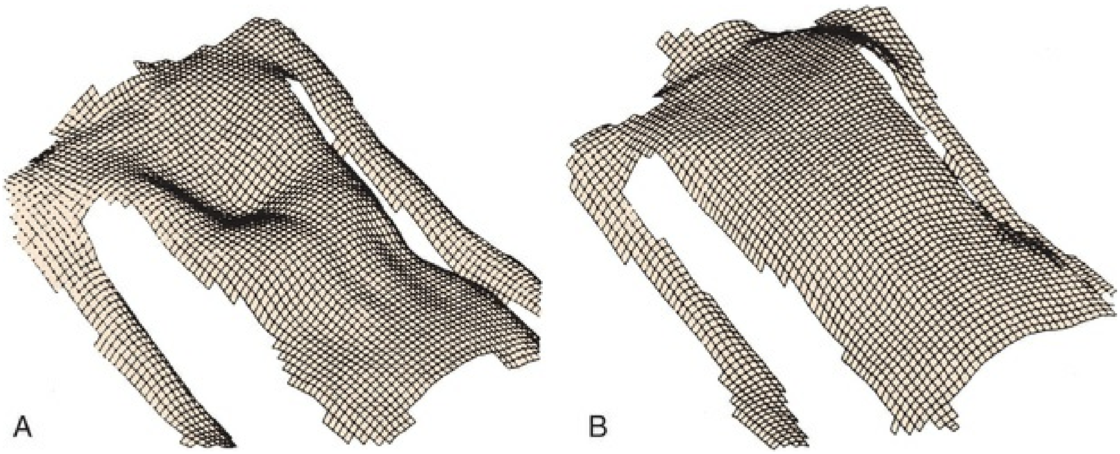

**FIG. 1.2** Optical markers augment the visual perception of chest wall deformities. In this example of rasterstereography, lines are projected onto the anterior thorax, and the surface image is computed as a regular network. The change of the funnel chest deformity before (A) and after surgery (B) is easily appreciated. In practice and at the bedside, the physician should inspect at different angles of illumination to enhance the visual perception of chest wall deformities. (From Hierholzer E, Schier F. Rasterstereography in the measurement and postoperative follow-up of anterior chest wall deformities. *Z Kinderchir*. 1986;41:267-271.)

The physician should measure the dimensions of the chest. Chest size and shape are influenced by ethnic and geographic factors that should be taken into account when measurements are compared with normative data. Andean children who live at high altitudes, for example, have larger chest dimensions relative to stature than children in North America. The chest circumference is usually taken at the mammillary level during midinspiration. In practice, mean readings during inspiration and expiration should be noted (Fig. 1.3A). Premature infants have a greater head circumference than chest circumference, while these measurements are very similar at term (see Fig. 1.3B). Malnutrition can delay the time at which chest circumference begins to exceed head circumference.

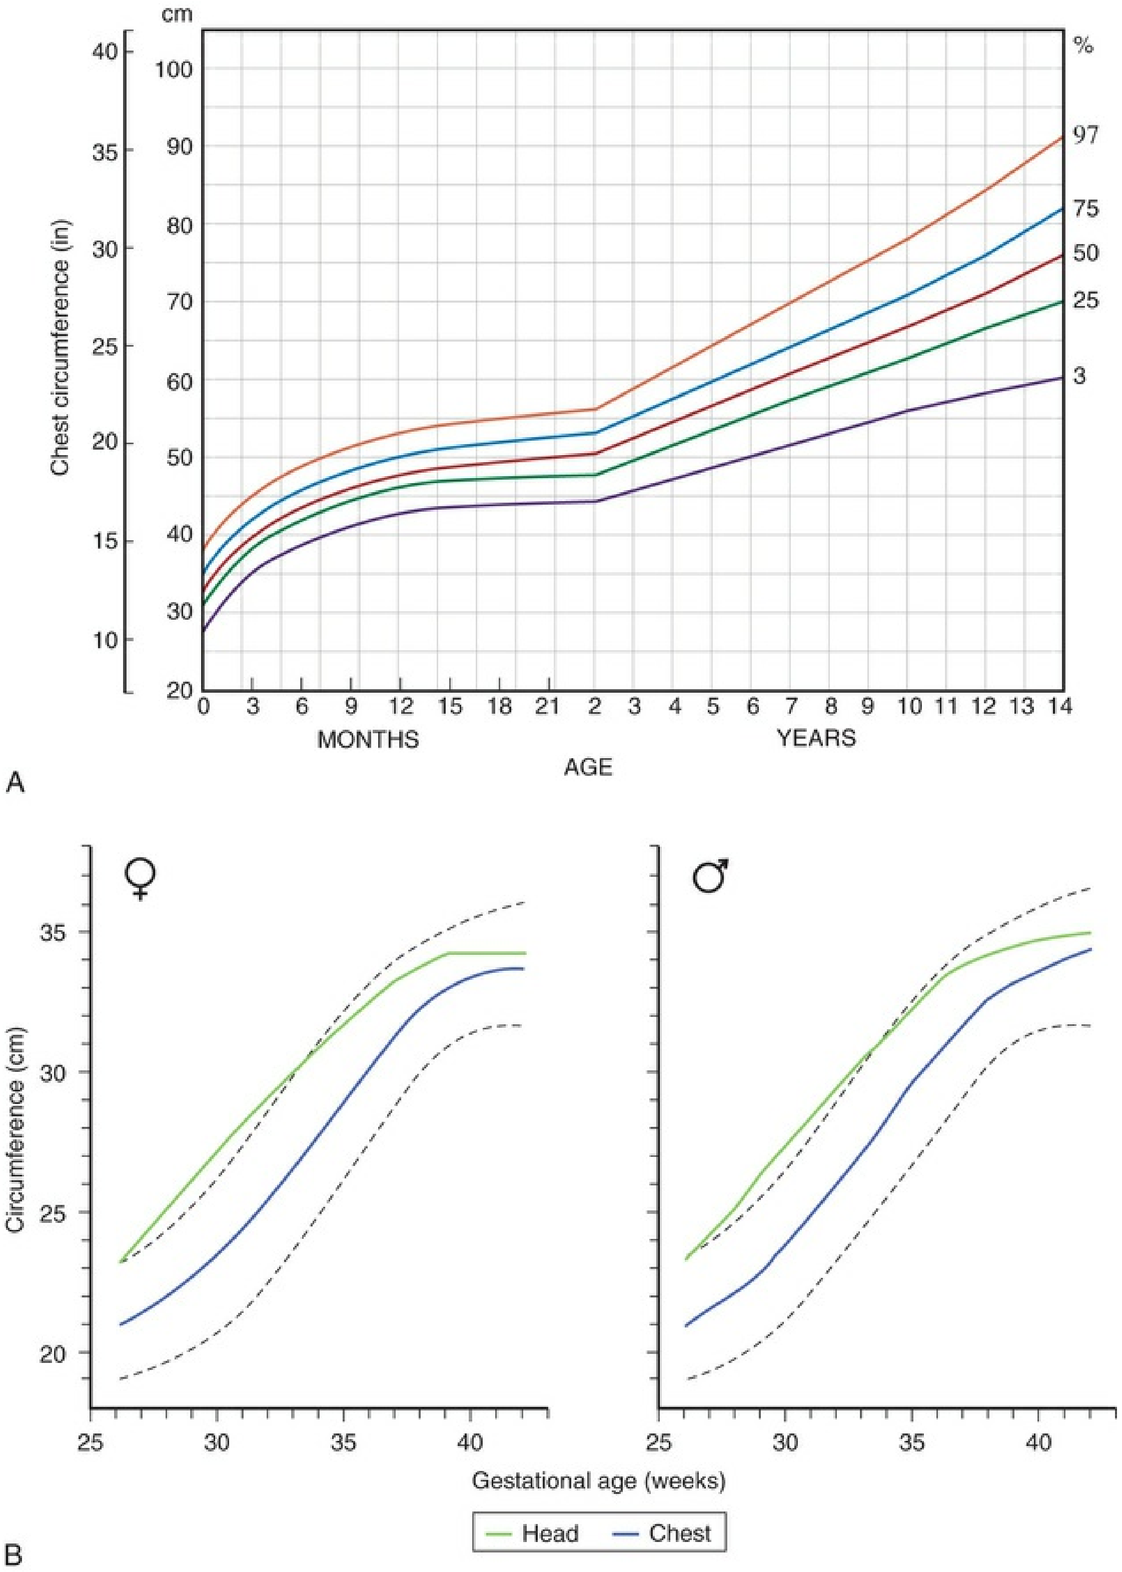

**FIG. 1.3** (A) Normal distribution of chest circumference from birth to 14 years. Tape measurements are made at the mammillary level during midinspiration. Before plotting the values on the graph, one should add 1 cm for males and subtract 1 cm for females between 2 and 12 years of age. (B) Normal distribution of chest

circumference from 26 to 42 weeks of gestation. The dotted lines indicate the 10th and 90th percentiles, respectively. Note that chest circumference is close to head circumference at term. ([A] From Feingold M, Bossert WH. Normal values for selected physical parameters. An aid to syndrome delineation. *Birth Defects*. 1974;10:14. [B] Data from Britton JR, Britton HL, Jennett R, et al. Weight, length, head and chest circumference at birth in Phoenix, Arizona. *J Reprod Med*. 1993;38:215.)

Further objective documentation of the chest configuration may include measurements of thoracic depth (anteroposterior [AP] diameter) and width (transverse diameter). The thoracic index, or the ratio of AP over transverse diameter, is close to unity in infants and decreases during childhood. Measurements should be taken with a caliper at the level of the nipples in upright subjects. Normative values for young children are available but dated (Fig. 1.4). Most of the configurational change of the chest occurs during the first 2 years and is probably influenced by gravitational forces after the upright position becomes common. Disease-related changes in thoracic dimensions occur either as potential causative factors (e.g., the elongated thorax with a stress distribution that favors spontaneous pneumothorax in lanky adolescents, particularly males who increase their thoracic height versus width more than females) or as a secondary event (e.g., the barrel-shaped chest in patients with emphysema and chronic hyperinflation of the lung).

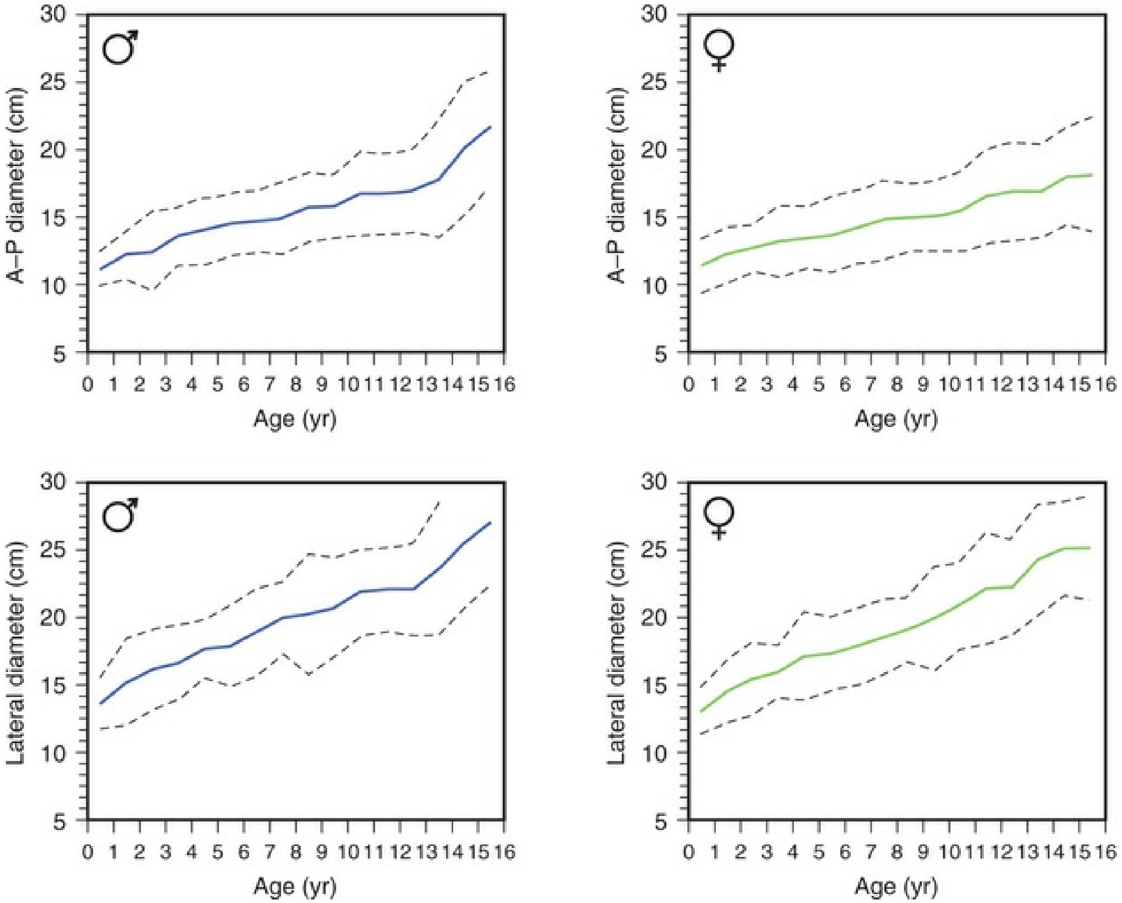

**FIG. 1.4** Mean values *(solid line)* ± SD *(dashed lines)* of the normal distribution of anteroposterior (AP) and lateral chest diameters in boys and girls. Caliper measurements are made at the mammillary level during midinspiration. *SD,* Standard deviation. (Data from Lucas WP, Pryor HB. Range and standard deviations of certain physical measurements in healthy children. *J Pediatr*. 1935;6:533-545.)

Inspection of the patient should also be directed to the extrathoracic regions. Many observations on the examination of the head and neck provide valuable clues to the physical diagnosis. Bluish coloration of the lower eyelid ("allergic shiners"); a bilateral fold of skin just below the lower eyelid (Dennie lines); and a transverse crease from "allergic salutes," running at the junction of the cartilaginous and bony portion of the nose, may all be found in atopic individuals. The physician should always examine the nose and document bilateral patency by occluding each side while feeling and listening for air flow through the other nostril. Even without a speculum, one can assess the anterior half by raising the nose tip with one thumb and shining a light into the nasal passageways. Color and size of the mucosa should be noted. The frequency of asymptomatic nasal polyps seems to be high. Most polyps arise from the mucosa of the ostia, clefts, and recesses in the ostiomeatal complex and have the appearance of white gelatinous grapes. Easily visible nasal polyps are common in patients with cystic fibrosis. Nasal polyposis may also be familial or associated with allergy, asthma, and aspirin intolerance.

The oropharynx should be inspected for its size and signs of malformation, such as cleft palate, and for signs of obstruction by enlarged tonsils. Evidence of chronic ear infections should be documented, and the areas over frontal and maxillary paranasal sinuses should be tested for tenderness. Inspection of the skin is important and may reveal the eczema of atopy. The finding of a scar that typically develops at the site of a successful bacillus Calmette-Guérin (BCG) vaccination may be relevant. In North American children, these scars are usually found over the left deltoid, but other sites, including buttocks and lower extremities, are also used for BCG inoculation in different parts of the world. Common physical findings such as cyanosis, clubbing, and the cardiovascular signs of pulmonary disease are discussed in more detail at the end of this chapter.

## Palpation

Palpation follows chest inspection to confirm observed abnormalities, such as swellings and deformations; to identify areas of tenderness or lymph node enlargement; to document the position of the trachea; to assess respiratory excursions; and to detect changes in the transmission of voice sounds through the chest. Chest palpation may offer the first physical contact with the patient, and it is very important for the physician to perform this procedure with warm hands.

Palpation should be done in an orderly sequence. Commonly, one begins with an examination of the head and neck. Cervical lymphadenopathy and tenderness over paranasal sinuses should be noted. Palpation of the oropharynx may be indicated to find malformations such as submucosal clefts or to identify causes of upper airway obstruction. The position of the trachea must be documented in every patient. This is a very important part of the physical chest examination because tracheal deviation most often indicates significant intrathoracic or extrathoracic abnormalities.

In the older child, the tracheal position is assessed by placing the index and ring fingers on both sternal attachments of the sternocleidomastoid muscles. The trachea is then felt between these landmarks with the middle finger on the suprasternal notch. In small children, palpation is done with one index finger sliding gently inward over the suprasternal notch. Looking for asymmetry, the physician should always make sure that the patient is in a straight position, and deformities (e.g., scoliosis) should be taken into account.

A very slight deviation of the trachea toward the right is normal. Marked deviations may indicate a pulling force toward the side of displacement (e.g., atelectasis) or a pushing force on the contralateral side (e.g., pneumothorax). The physician should note whether the displacement is fixed or whether there is a pendular movement of the trachea during inspiration and expiration that may suggest obstruction of a large bronchus. Posterior displacement of the trachea may occur with anterior mediastinal tumors or barrel chest deformities, whereas an easily palpable anteriorly displaced trachea is sometimes seen with mediastinitis. In patients with airway obstruction and respiratory distress, retractions of the suprasternal fossa may be seen, and a "tracheal tug" may be felt by the examiner.

Placing the hands on both sides of the lateral rib cage, the physician should feel for symmetry of chest expansion during regular and deep breathing maneuvers. Slight compression of the chest in the transverse and AP directions may help to localize pain from lesions of the bony structures. Voice-generated vibrations are best felt with the palms of both hands just below the base of the fingers placed over corresponding sites on the right and left hemithorax. Asymmetric transmission usually indicates unilateral intrathoracic abnormalities. The patient is asked to produce low-frequency vibrations of sufficient amplitude by saying "ninety-nine" in a loud voice. In young infants, crying may produce the vibrations that are felt as tactile fremitus over the chest wall. This fremitus is decreased if an accumulation of air or fluid in the pleural space reduces transmission. Small consolidations of the underlying lung will not diminish the tactile fremitus as long as the airways remain open, whereas collapse of the airways and atelectasis will reduce the transmission of vibratory energy if larger portions of the lung are affected.

## Percussion

Percussion is used to set tissues into vibration with an impulsive force so that their mechanical and acoustic response can be studied. If the vibrations are not damped and continue for a significant amount of time, the perceived sound will be resonant or "tympanic," whereas rapid attenuation of the vibrations will lead to a flat or "dull" percussion note. The former occurs when there is a large acoustic mismatch (e.g., tissue overlying an air-filled cavity), whereas the latter occurs when the underlying tissue is similar to the surface tissue and vibratory energy propagates away quickly. Structures that absorb energy when struck by a sound at their natural frequency continue vibrating after the initial sound is gone and are called *resonant.* The fundamental resonance of the thorax depends on body size and is about 125 Hz for adult males, between 150 and 175 Hz for adult females, and between 300 and 400 Hz for small children.

Chest percussion in children is performed by light tapping with the middle finger (the plexor) on the middle or terminal phalanx of the other hand's middle finger (the pleximeter). The pleximeter should be placed firmly but not hard, and care should be taken that other fingers do not touch the chest wall, which may cause artificial damping of the percussion note. Percussion should be gentle, with quick perpendicular movements of the plexor originating from the wrist (Fig. 1.5). The patient should be relaxed during the examination because tension of the chest wall muscles may alter the percussion note. More importantly, chest deformities and scoliosis in particular will have a significant effect on percussion findings.

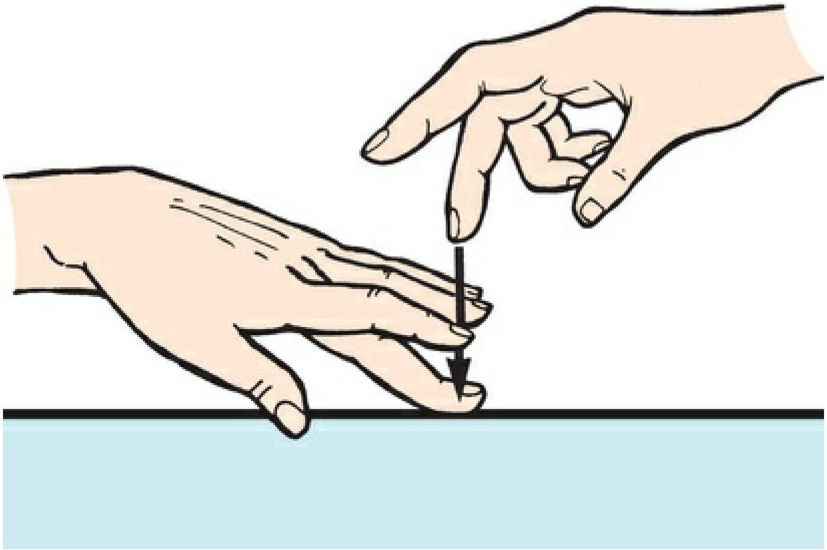

**FIG. 1.5** Percussion in children should be done with gentle perpendicular movements from the wrist and tapping of the plexor finger *(right)* on the middle or terminal phalanx of the pleximeter finger *(left).* The contact area of the pleximeter on the chest should be small, and other fingers should not touch the surface to avoid damping of the vibrations.

Symmetric sites over the anterior, lateral, and posterior surface of the chest should be compared in an orderly fashion. As with chest auscultation, findings should be reported with reference to standard external anatomic landmarks (Fig. 1.6). The ribs and vertebral spinous processes are used for horizontal mapping. The level at which the tympanic lung resonance changes to a dull percussion note should be defined over the posterior chest during maximal inspiration and expiration to delineate the lung borders and their respiratory excursions.

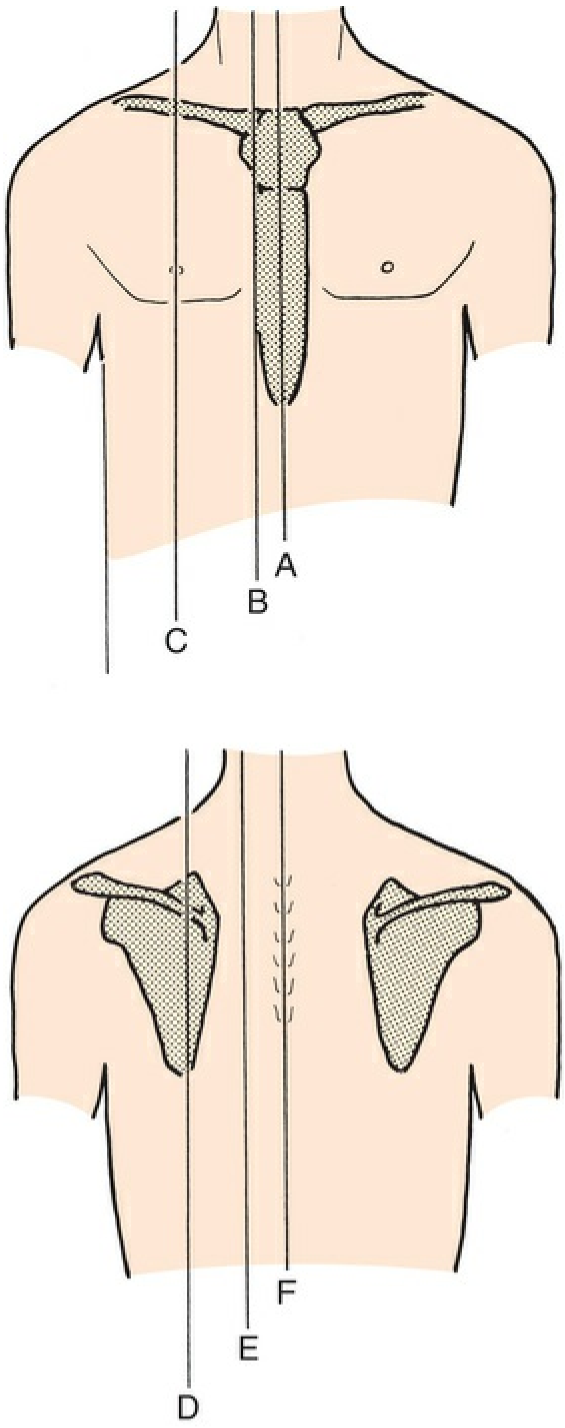

**FIG. 1.6** Vertical reference lines of the chest. The center line is indicated anteriorly by the suprasternal notch (A) and posteriorly by the spinous processes (F). The sternal (B) and midclavicular (C) lines over the front, and the scapular (D) and paravertebral (E) lines over the back provide longitudinal landmarks of the thorax. From a lateral view, the midaxillary line is used for orientation. Horizontal reference points are the supraclavicular and infraclavicular fossae, Ludwig angle (junction of the second rib at the sternum), the

mammillae (normally at the fourth rib), and the epigastric angle. Posteriorly, the prominent spinous process of the seventh cervical vertebra and the supraspinous and infraspinous fossae of the scapulae provide markers for orientation.

Subjective assessment of percussion note differences includes both acoustic and tactile perception. Tympanic, lower-pitched percussion notes mean less-damped vibrations of longer duration, which are felt by the pleximeter finger and heard by the examiner. These resonant sounds can be exaggerated, or hyperresonant, over hyperinflated lungs but also in some otherwise healthy thin individuals. Observer agreement on this sign is relatively poor unless the finding is unilateral.

Dull sounds with higher frequencies correspond to vibrations that die away quickly. Dullness replaces the normal chest percussion note when fluid accumulates in the pleural space or when consolidation occurs in the underlying pulmonary parenchyma close to the chest wall. Similar to the vibrations generated by percussion, the vibrations from the patient's voice (“say ‘ninety-nine’ ”) will also not be felt under these circumstances. The tactile fremitus is equally absent over areas of pneumothorax, whereas percussion, as noted above, should have a hyperresonant quality.

Conventional percussion cannot detect small pulmonary lesions located deeply within the thorax. Auscultatory percussion has been proposed to overcome this limitation. This technique combines light percussion of the sternum with simultaneous auscultation over the posterior chest. A decrease in sound intensity is believed to indicate lung disease. The method is of little value, however, because even large intrathoracic lesions can remain undetected since percussion sounds may either be totally absorbed within the lung or may travel as transverse waves along the thoracic bones.

## Auscultation

Auscultation is arguably the most important part of the physical chest examination. The subjective perception of respiratory acoustic signs is influenced by the site and mode of sound production; by the modification of sound on its passage through the lung, chest wall, and stethoscope; and, finally, by the auditory system of the examiner. Knowledge about these factors is necessary to appreciate fully the wealth of information that is contained in the acoustic signs of the thorax.

## Thoracic Acoustics

Observations on sound generation in airway models and electronic analyses of respiratory sounds suggest a predominant origin from complex turbulences within the central airways. The tracheal breath sound heard above the suprasternal notch is a relatively broad-spectrum noise, ranging in frequency from less than 100 Hz to greater than 2000 Hz. Resonances from the trachea and from supraglottic airways “color” the sound (Fig. 1.7). The lengthening of the trachea with growth during childhood causes lower tracheal resonance frequencies. A dominant source of tracheal breath sounds is turbulence from the jet flow at the glottic aperture. However, narrow segments of the supraglottic passages also contribute to sound generation. There is a very close relationship between air flow and tracheal sound intensity, particularly at high frequencies. In the presence of local narrowing (e.g., in children with subglottic stenosis), flow velocity at the stenotic site is increased, and so is the tracheal sound intensity. Relating tracheal sound levels to air flow measured at the mouth can provide information about changes during therapy. Auscultation over the trachea will provide some information under these circumstances, but objective acoustic measurements are required for accurate comparisons.

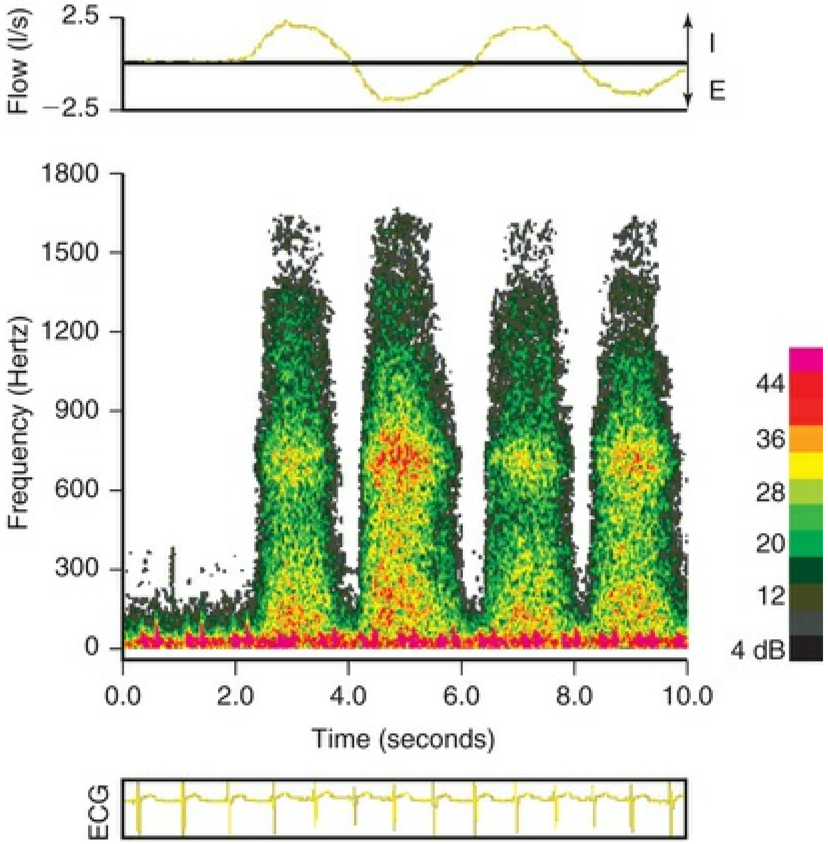

**FIG. 1.7** Digital respirosonogram of sounds recorded over the trachea of a healthy young man. Time is on the horizontal axis, frequency is on the vertical axis, and sound intensity is shown on a scale from *red (loud)* over *orange and yellow (medium)* to *green, gray, and black (low).* Air flow is plotted at the top, with inspiration above and expiration below the zero line. The sonogram illustrates the broad range of tracheal sounds during both inspiration and expiration. There is a distinct pause between the respiratory phases. Expiration is louder than inspiration, and resonance is apparent around 700 Hz. In this example, the subject was holding his breath at the beginning. During this respiratory pause, heart sounds below 200 Hz are easily identified by their temporal relation to the simultaneously recorded electrocardiogram (ECG).

Basic “normal” lung sounds heard at the chest surface are lower in frequency than tracheal sounds because sound energy is lost during passage though the lungs, particularly at higher frequencies. However, lung sounds extend to frequencies higher than traditionally recognized. More recent observations on the effects of gas density indicate that lung sounds at frequencies above 400 Hz are mostly generated by flow turbulence. At lower frequencies, other mechanisms that are not directly related to air flow (e.g., muscle noise and thoracic cavity resonances) have prominent effects on lung sounds, and gas density effects are less obvious. Inspiratory lung sounds show little contribution of noise generated at the glottis. Their origin is likely more peripheral (i.e., in the main and segmental bronchi). Expiratory lung sounds appear to have a central origin and are probably affected by flow convergence at airway bifurcations (Fig. 1.8).

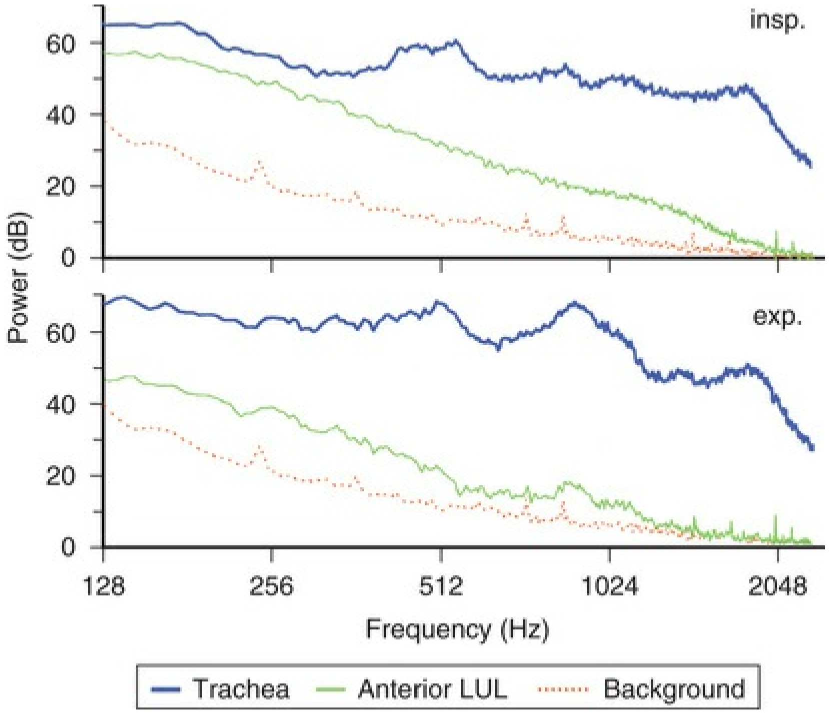

**FIG. 1.8** Average spectra of respiratory sounds at air flow of 1.5 ± 0.3 L/s, recorded simultaneously at the suprasternal notch (trachea) and at the second intercostal space in the midclavicular line on the left (anterior left upper lobe [LUL]) of a healthy 12-year-old boy. The average sound spectrum during breath holding at resting end expiration (background) is plotted for comparison. Inspiratory lung sounds are louder than expiratory sounds, while the opposite is true for tracheal sounds. Lung sound intensity is clearly above background at frequencies as high as 1000 Hz. Expiratory lung sounds show some of the same spectral peaks that are present in tracheal sounds.

Sound at different frequencies takes different pathways on the passage through the lung. Low-frequency sound waves propagate from central airways through the lung parenchyma to the chest wall. At higher frequencies, the airway walls become effectively more rigid and sound travels further down into the airways before it propagates through lung tissue. This information cannot be gathered on subjective auscultation but requires objective acoustic measurements. A trained ear, however, will recognize many of the findings that are related to these mechanisms. For example, lung sounds in healthy children and adults are not necessarily equal at corresponding sites over both lungs. In fact, expiratory sounds are typically louder at the right upper lobe compared with the left side. Similar asymmetry has been recognized when sound is introduced at the mouth and measured at the chest surface. A likely explanation for this asymmetry is the effect on sound propagation by the cardiovascular and mediastinal structures to the left of the trachea. Asymmetry of lung sounds is also noticeable in most healthy subjects during inspiration when one listens over the posterior lower chest. The left side tends to be louder here, probably because of the size and spatial orientation of the larger airways due to the heart.

Objective acoustic measurements have also helped to clarify the difference between lung sounds in newborn infants and in older children. The most obvious divergence occurs in lung sounds at low frequencies where newborn infants have much less intensity. This may be explained by thoracic and airway resonances at higher frequencies in newborn infants and perhaps also by their lower muscle mass. Lung sounds at higher frequencies are similar between newborn infants and older children (Fig. 1.9).

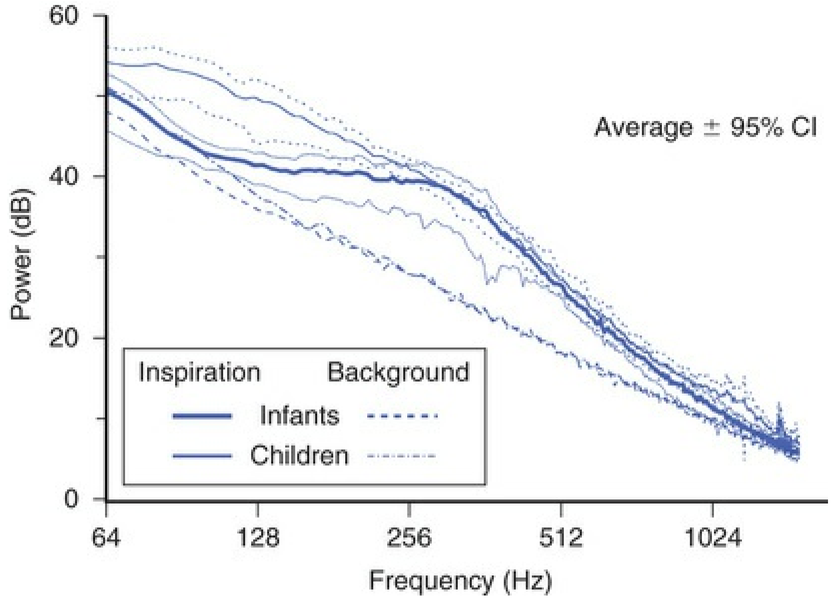

**FIG. 1.9** Average spectra of inspiratory lung sounds, recorded over the posterior basal segment of the right lung in healthy newborn infants ($n$ = 10) and children ($n$ = 9) at air flows of 15 mL/s per kilogram. The spectra of background noise at resting end expiration are plotted for comparison. Dotted lines mark the 95% confidence intervals (CIs). Note the similarity of spectral slopes in newborn infants and older children at frequencies above 300 Hz and the significantly reduced sound power at lower frequencies in newborns. (Data from Pasterkamp H, Powell RE, Sanchez I. Lung sound spectra at standardized air flow in normal infants, children, and adults. *Am J Respir Crit Care Med*. 1996;154:424-430.)

Adventitious respiratory sounds usually indicate respiratory disease. Wheezes are musical, continuous (typically longer than 100 ms) sounds that originate from oscillations in narrowed airways. The frequency of the oscillation depends on the mass and elasticity of the airway wall as well as on local air flow. Widespread narrowing of airways in asthma leads to various pitches, or polyphonic wheezing, whereas a fixed obstruction in a larger airway produces a single wheeze, or monophonic wheezing. Expiratory wheezing is related to flow limitation and can be produced by normal subjects during forced expiratory maneuvers. The situation is less clear for wheezing during inspiration, which is common in asthma but cannot be produced by healthy subjects unless it originates from the larynx (e.g., in vocal cord dysfunction).

Very brief and localized inspiratory wheezes may be heard over areas of bronchiectasis.

Crackles are nonmusical, discontinuous (<20 ms duration) lung sounds. Crackle production requires the presence of air-fluid interfaces and occurs either by air movement through secretions or by sudden equalization of gas pressure. Another mechanism may be the release of tissue tension during sudden opening or closing of airways. Crackles are perceived as fine or coarse, depending on the duration and frequency of the brief and dampened vibrations created by these mechanisms. There may be a musical quality to the sound if a short oscillation occurs at the generation site. This has been called a *squawk* and may appear during inspiration, typically in patients with interstitial lung diseases but also in some patients with pneumonia or bronchiectasis. Fine crackles during late inspiration are common in restrictive lung diseases and in the early stages of congestive heart failure, whereas coarse crackles during early inspiration and during expiration are frequently heard in chronic obstructive lung disease. Fine crackles are usually inaudible at the mouth, whereas the coarse crackles of widespread airway obstruction can be transmitted through the large airways and may be heard as clicks with the stethoscope held in front of the patient's open mouth. Some crackles over the anterior chest may occur in normal subjects who were breathing at low lung volumes, but they will disappear after a few deep breaths.

Several other abnormal respiratory sounds are not generated in intrathoracic airways. Pleural rubs originate from mechanical stretching of the pleura, which causes vibration of the chest wall and local pulmonary parenchyma. These sounds can occur during both inspiration and expiration. Their character is like that of creaking leather and is similar in some ways to pulmonary crackles. *Stridor* refers to a more or less musical sound that is produced by oscillations of critically narrowed extrathoracic airways. It is therefore most commonly heard during inspiration. *Grunting* is an expiratory sound, usually low-pitched and with musical qualities. It is produced in the larynx when vocal cord adduction is used to generate positive end-expiratory pressures, such as in premature infants with immature lungs and surfactant deficiency. *Snoring* originates from the flutter of tissues in the pharynx and has a less musical quality. It may be present during both inspiration and expiration.

There may also be cardiorespiratory sounds. These are believed to occur when cardiac movements cause regional flows of air in the surrounding lung. Because of its synchronicity with the heartbeat, this sound may be mistaken for a cardiac murmur. It can be identified by its "vesicular sound" quality and its exaggeration during inspiration and in different body positions.

At the boundary between different tissues, reflection of sound may occur and sound transmission may decrease, depending on the matching or mismatching of the tissue impedances. Many of the acoustic signs of the chest are explained on the basis of impedance matching alone. The stethoscope is basically an impedance transformer that reduces sound reflection at a mismatched interface, namely, body surface to air. Because it is the only part of the sound transmission pathway that can be kept constant, it is best to always use the same stethoscope. The choice of a bell- or a diaphragm-type stethoscope depends on individual preference. Diaphragm chest pieces can be placed more easily and with less pressure on small chests with narrow intercostal spaces. Compared with bell-type stethoscopes, they tend to deemphasize frequencies below 100 Hz. Both the bell-type and the diaphragm stethoscopes show some attenuation at frequencies above 400 Hz.

## Technique of Auscultation

Ideally, auscultation of the chest should be performed in a quiet room; however, with pediatric patients the usual setting may be anything but quiet. Fortunately, the human auditory system allows selective evaluation of acoustic signals even when they occur in the presence of much louder surrounding noises. This psychoacoustic phenomenon, known as the "cocktail party effect," at present cannot be reproduced by modern electronic techniques, which is but one of the reasons for the lasting popularity of the stethoscope.

This instrument, the most widely used in clinical medicine since its introduction almost 200 years ago, carries symbolic value for the health care profession, much like a modern staff of Aesculapius. Every child knows that doctors have stethoscopes. The physician should use this to advantage when assessing pediatric patients by encouraging children to listen themselves to their heartbeats and breathing sounds. Even infants may be fascinated as long as the stethoscope is shiny. Ice cold chest pieces, on the other hand, turn off most patients.

The patient should be in a straight position during auscultation because incurvature of the trunk may lead to artificial side differences of sound production and transmission. In newborns and young infants, a straight position may be best achieved when they are supine. Infants and toddlers will often be assessed while their parents hold them on their laps. Beginning auscultation on the back of these young patients will provoke less anxiety than a frontal approach. Older children can be examined in the sitting or standing position. The number of sites over the chest that are assessed during auscultation will be determined by the clinical situation. Ideally, all segments of the lung should be listened to, but this may not be possible, particularly in very young children.

Because the intensity of respiratory sounds is related to air flow, sufficiently deep respirations (with flow >0.5 L/s) are needed for a good sound signal. An older patient will cooperate and breathe deeply through an open mouth. With infants and young children, however, one may have to rely on sounds made during sighs or deep inspirations in between crying. On the other hand, normal breath sounds can mask the presence of some adventitious sounds (e.g., fine crackles of low intensity). Asking the patient to take very slow, deep breaths with less air flow than is needed to generate normal breath sounds can help to unmask these adventitious sounds.

The physician should make note of the lung sound intensity over different areas of the chest in a qualitative way, keeping in mind that this intensity reflects both local sound generation and sound transmission characteristics of the thorax. It is therefore not correct to speak of local “air entry” when one actually refers to local breath sound intensity. Decreased breath sounds, for example, are common in asthma even when normal blood gases indicate that air entry has to be adequate. Obviously, a qualitative distinction between the absence or presence of local breath sounds will be easier than attempts at quantification. Also, when the stethoscope is placed over any given location, it is not known how large an area of the underlying lung is actually being assessed. In adult subjects, moving the chest piece of the stethoscope by 10 cm will position it to receive sound from entirely different lung units, but similar data for children are not available.

Assessment of regional ventilation by thoracic acoustic signs becomes more meaningful when two sites are compared simultaneously. Differential auscultation with special stethoscopes that employ two chest pieces or a single divided chest piece has not become popular in clinical practice. Nevertheless, comparative auscultation is absolutely essential for airway management in the emergency department and intensive care unit for assessment of endotracheal tube position or for identification of the side of a pneumothorax. Listening simultaneously to two homologous sites over both lungs may also help to detect local abnormalities. With local airway narrowing, the maximum sound intensity over the affected side may become sufficiently delayed to be perceived as "phase heterophony." In some cases, breath sounds may still be audible over the affected side after inspiratory efforts have ceased. This "post-effort" breath sound is a sign of incomplete airway obstruction.

There are special circumstances in which only the presence or absence of breath sounds is of interest (e.g., during transportation of critically ill patients in noisy vehicles and during resuscitation in the emergency department). Under these conditions, and when a firm attachment of the chest piece is important, a self-adhering stethoscope, based on negative suction pressure within the bell of the chest piece, may be applied. New techniques of adaptive electronic filtering are being used in stethoscopes that are optimized for use in very noisy environments.

Respiratory sounds should be documented according to their location and character. Normal projections of lobar borders to the surface of the chest are shown in Fig. 1.10. These may be distorted by local pulmonary disease, and mapping of respiratory sounds should therefore be done with reference to external anatomic landmarks (see Fig. 1.6). The examiner should be familiar with the segmental structure of the underlying lung.

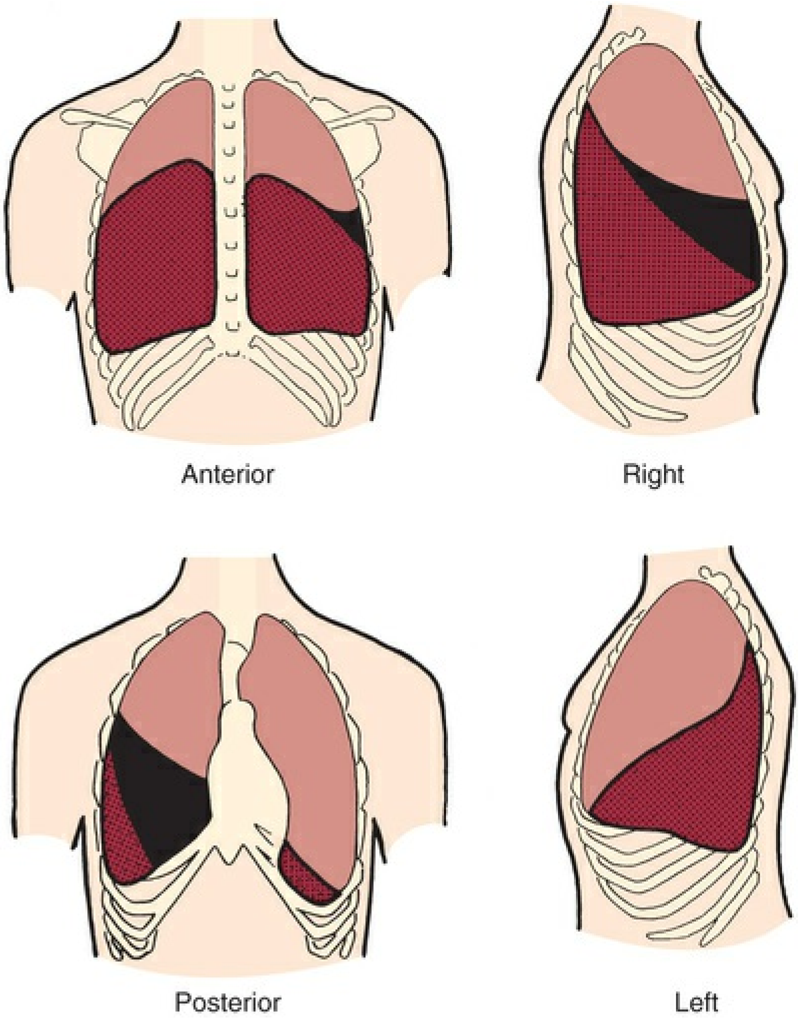

**FIG. 1.10** Projections of the pulmonary lobes on the chest surface. The upper lobes are *pink*, the right-middle lobe is *black*, and the lower lobes are *red.*

Respiratory sound characteristics include the intensity (amplitude), pitch (predominant frequency), and timing during the respiratory cycle. Also, sounds will have a particular timbre (character) caused by the presence of resonances and overtones. Unfortunately, the terminology in use for the description of respiratory sounds is still confusing and imprecise. During a symposium on lung sounds in Tokyo in 1985, an attempt was made to achieve a global and uniform nomenclature for breath sounds (Table 1.1). More recently, a Task Force of the European Respiratory Society documented the current use of terminology in Western languages and recommended some modifications. The earlier and current recommendations for classification of adventitious lung sounds are summarized in Table 1.2, which summarizes the mechanisms and sites of generation, acoustic characteristics, and clinical relevance of the major categories of respiratory sounds.

## Table 1.2

## Respiratory Sounds

| Basic Sounds | Mechanisms | Origin | Acoustics | Relevance |
|---|---|---|---|---|
| Lung | Turbulent flow, vortices, other | Central (expiration), lobar to segmental airways (inspiration) | Low pass filtered noise (<100 to >1000 Hz) | Regional ventilation, airway caliber |
| Tracheal | Turbulent flow, | Pharynx, larynx, | Noise with resonances (<100 | Upper airway |

| | | | | |
|---|---|---|---|---|
| | flow impinging on airway walls | trachea, large airways | to >3000 Hz) | configuration |
| **ADVENTITIOUS SOUNDS** | | | | |
| Wheezes | Airway wall flutter, vortex shedding, other | Central and lower airways | Sinusoidal (<100 to >1000 Hz, duration typically >80 ms) | Airway obstruction, flow limitation |
| Rhonchi | Rupture of fluid films, airway wall vibration | Larger airways | Series of rapidly dampened sinusoids (typically <300 Hz and duration <100 ms) | Secretions, abnormal airway collapsibility |
| Crackles | Airway wall stress-relaxation | Central and lower airways | Rapidly dampened wave deflections (duration typically <20 ms) | Airway closure, secretions |

Modified from Pasterkamp H, Kraman SS, Wodicka GR. State of the art. Respiratory sounds—advances beyond the stethoscope. *Am J Respir Crit Care Med*. 1997;156:974-987.

A basic grouping into musical, continuous sounds of long duration and nonmusical, discontinuous sounds of short duration is made, with the former being referred to as *wheezes* and the latter as *crackles*. Furthermore, musical adventitious sounds or wheezes may be classified as high-pitched or low-pitched. Some use the term *rhonchus* for low-pitched wheezes (<200 Hz), whereas others describe the poorly characterized “secretion sounds,” which share musical and nonmusical qualities, as *rhonchi*. Crackles are subclassified as fine or coarse. Basic normal sounds include tracheal and lung sounds. Adventitious sounds may be heard over the chest and sometimes also over the trachea or at the mouth (Fig. 1.11). Other respiratory sounds should be specified, such as pleural rubs, expiratory grunting, and inspiratory stridor. Historical terms such as *rales* should be abandoned, and flowery descriptions such as “raspy” or “blowing” breath sounds should not be used because these adjectives are even less well defined than the suggested terms.

**FIG. 1.11** Categories of respiratory sounds. (From Pasterkamp H, H, Brand PL, Everard M, et al. Towards the standardisation of lung sound nomenclature. *Eur Respir J.* 2016;47:724.)

Several auscultatory signs are based on the transmission of voice sounds. Speech sounds have a fundamental note of about 130 Hz in men and 230 Hz in women, with overtones from 400 to 3500 Hz. Vowels are produced when particular pairs of overtones or formants are generated. On passage through the lung, the higher-frequency formants are filtered, and speech heard over the chest becomes a meaningless mumble. With consolidation and transmission of higher-frequency components, however, speech may become intelligible. This occurs with normal speech (bronchophony) and with whispered voice (pectoriloquy). There may be a change in vowels from *e* to *a* over areas of lung consolidation. The acoustic basis for these phenomena is the same as for bronchial breath sounds. The American Thoracic Society and the American College of Chest Physicians recommend the term *egophony* for all of these findings.

## Taste and Smell

A complete physical examination extends beyond the perception of vision, hearing, and touch. Olfactory impressions should also be documented, even if they are subtle. Malodorous breath is easily noticed and may, particularly if chronic, indicate infection within the nasal or oral cavity (e.g., paranasal sinusitis), nasal foreign body, or dental abscess. *Extraoral halitosis* may also originate from intrathoracic infections, such as lung abscess or bronchiectasis, and it may also be noted in patients with GER. Nowadays physicians rarely use their taste buds to make a medical diagnosis. One particular disease of the respiratory tract in children, however, lends itself to gustatory diagnosis. Most often the discovery is made by the mother of a patient with cystic fibrosis who notices that the skin of her child tastes abnormally salty.

## Common Signs and Symptoms of Chest Disease in Children

There are several common complaints and presentations of children with chest diseases that deserve a more detailed description. In particular, cough and sputum production, noisy breathing, wheezing, cyanosis, digital clubbing, cardiovascular signs, exercise limitation, dyspnea, and chest pain need to be discussed.

### Cough and Sputum

Cough is not an illness by itself, but it is a cardinal manifestation in many chest diseases. Cough is probably the single most common complaint in children presenting to the physician and even in the absence of any underlying chronic lung pathology can cause children and their caregivers significant amounts of distress. The act of coughing is a reflex aimed at removal of mucus and other material from the airways that follows the stimulation of cough or irritant receptors. These receptors are located anywhere between the pharynx and the terminal bronchioles. They send their afferent impulses via branches of the glossopharyngeal and vagus nerves to the cough center in the upper brainstem and pons. The efferent signals travel from the cough center via vagus, phrenic, and spinal motor nerves to the larynx and diaphragm as well as to the muscles of the chest wall, abdomen, and pelvic floor. Cortical influences allow the voluntary initiation or suppression of cough (see Chapter 8).

There are three phases of coughing: (1) deep inspiration; (2)

closure of the glottis, relaxation of the diaphragm, and contraction of expiratory muscles; and (3) sudden opening of the glottis. During the second phase, intrathoracic pressures up to 300 mm Hg can be generated and may be transmitted to the vascular and cerebrospinal spaces. Air flow velocity during the third phase is highest in the central airways and may reach three fourths the speed of sound. This speed depends on the sudden opening of the glottis and influences the success of expectoration. Patients with glottic dysfunction and those with tracheostomies may therefore have a less effective cough.

Stimuli that cause coughing may originate centrally, such as in psychogenic cough, or they may be pulmonary, located either in the major airways or in the pulmonary parenchyma. Also, cough can be provoked by nonpulmonary causes, such as irritation of pleura, diaphragm, or pericardium and even through stimulation of Arnold nerve (a branch of the vagus) by wax or foreign bodies in the external ear. Cough is part of the innate defense mechanism, and even a healthy child may cough several times a day. However, this cough should not be bothersome to the child, should disappear when the child is asleep and is frequently not noticed by families or children.

Acute cough is defined as lasting less than 3 weeks, while definitions of chronic cough vary from 4 to 8 weeks duration. The most frequent cause of acute cough is viral respiratory infections and these are usually self-resolving illnesses. In preschool children 50% will have their cough resolve within 10 days and 90% resolve by 25 days. On history there should be a clear viral prodrome associated, and while the symptoms may worsen during the first few days, the cough should be clearly improving with time. Postinfectious cough that lasts >3 weeks may be associated with mycoplasma or pertussis infections especially when there was a history of coughing paroxysms or posttussive emesis. It is important to note that children have on average of five to eight respiratory infections a year. Higher rates may be seen in the very young and in larger households and daycare settings. Children presenting with chronic cough may actually have symptoms from recurrent viral infections. For many parents, these episodes will blend together and they will report their child is “always coughing.” Therefore a careful history is particularly important: is there a waxing and waning course of the cough? Is worsening associated with new onset of rhinorrhea? Are there are occasional symptom-free periods, for example, when the child is away from the daycare during family vacations, or during summer. It is also important to have a complete history to exclude any specific disease pointers.

In assessing chronic cough, the detailed history should define the nature of the cough; whether it is dry, hacking, or brassy; and whether it is productive by sound and appearance. A wet sounding cough is reliably associated with large amounts of secretions on bronchoscopy. In young children, expectoration is unusual, but if observed, the quantity and quality of sputum should be noted. In particular, the physician should inquire about the color and odor of the expectorate and about the presence of blood in the sputum. The yellow-green color of purulent sputum results from the cellular breakdown of leukocytes and the liberation of myeloperoxidase from these cells. This finding indicates the retention of secretions and does not necessarily reflect an acute infection.

The timing of coughing is important, and its relationship to daily routines should be sought. Cough during or after drinking occurs with aspiration. Long-term chronic aspiration, especially in children with neurologic abnormalities, may take the form of silent aspiration. Clinicians should maintain an increased index of suspicion of chronic aspiration in children with neurodevelopmental abnormalities and those with syndromes associated with structural abnormalities, for example, tracheoesophageal fistula or laryngeal-esophageal clefts. Directly observing a feeding in clinic can provide valuable information. A cough that occurs after eating solids only may be associated with esophageal pathology such as eosinophilic esophagitis.

Coughing after a witnessed choking episode is highly suspicious for a retained foreign body aspiration. As foreign body aspirations, especially in preschool children, are often unwitnessed, the clinician should also consider this if there was a sudden onset to the cough or if the onset of cough in a previously healthy preschooler was not associated with signs of an upper respiratory tract infection.

A history of a cough that is progressively worsening or associated with weight loss, night sweats, and fevers may be related to significant infections such as mycobacterium tuberculosis or expanding malignancies compressing the trachea.

A chronic productive cough, especially if it is year-round or early in the morning is typical for bronchiectasis and related diseases such as cystic fibrosis (CF) and primary ciliary dyskinesia (PCD).

A cough with a neonatal onset can be associated with congenital infections, (e.g., chlamydia, especially if it has a staccato nature), with congenital airway or chest malformations (especially if there is an associated wheeze or stridor), and with recurrent aspiration or diseases such as CF and PCD. The latter especially is associated with an early onset of daily cough in the first 6 months of age and neonatal respiratory distress.

Nighttime cough may be related to asthma or to postnasal drip. Cough due to asthma is typically associated with a history of wheezing, with exertional symptoms, an atopic history, or a previous response to asthma medications. Seasonal worsening or coughing on exposure to potential allergens should be documented. In assessing nocturnal cough, the clinician should keep in mind that there is poor correlation between parental report and objective recordings of nocturnal cough. One factor that may influence this is the distance between the child and parents' bedrooms.

Cough that is associated with food regurgitation, throat clearing, supine position, or throat, chest or abdominal pain may be associated with GER. However, it is often the chronic respiratory symptoms that can worsen GER rather than vice versa.

Cough that is honking or loud, brassy and sometimes demonstrative in nature, and that resolves when the child is asleep, can be due to a psychogenic cough. An associated history of psychosocial stressors is important to obtain when considering this diagnosis.

Environmental factors can play an important role in the cause or exacerbation of a cough. The physician should ask about active and passive smoking, keeping in mind that, regrettably, there are quite a few children as young as 8 years of age who smoke regularly.

A detailed diary to note the frequency and timing of cough can be of value. When age appropriate, the patient should be encouraged to maintain the diary with the help of their caregiver as this appears to correlate better with objective measurement of cough.

Technology to record, quantify, and characterize cough is being developed. Some acoustic characteristics of cough are quite specific for certain diseases, such as the sound of a barking seal in viral croup or the whooping noise in pertussis. In patients with chronic cough, the physician should weigh the possible causes in view of their prevalence at different ages (Table 1.3). Also, complications of severe coughing paroxysms, such as pneumothorax, cough syncope, or nonsyncopal neurologic manifestations, should be considered. Regarding the last, the physician should inquire about lightheadedness, headache, visual disturbance, paresthesia, and tremor.

**Table 1.3**

**Causes of Chronic Cough**

| Infant | Preschool | School Age/Adolescence |
|---|---|---|
| Congenital anomalies | Foreign body | Reactive |
| Tracheoesophageal fistula | Infections | Asthma |
| Neurologic impairment | Viral | Postnasal drip |
| Infections | Mycoplasma | Infections |
| Viral | Bacterial | Mycoplasma |
| Chlamydia | Reactive | Irritative |
| Bacterial (pertussis) | Asthma | Smoking |
| Cystic fibrosis | Cystic fibrosis | Air pollution |
| — | Irritative | Psychogenic |
| — | Passive smoking | — |

Data modified from Eigen H. The clinical evaluation of chronic cough. *Pediatr Clin North Am*. 1982;29:67.

# Noisy Breathing

Quite frequently a child is brought to the physician's attention because of abnormal breathing noises. This noise may be a nonmusical hiss, much like the one produced in normal subjects at increased rates of ventilation, or it may have the musical qualities of stridor and snoring. Also, bubbling and crackling noises may be heard, and the tactile perception may contribute to the impression of a “rattly” chest in these patients.

The physician should focus attention on the noise-generating structures of the extrathoracic airways that are located at points of anatomic narrowing (e.g., the nasal vestibule, the posterior nasal orifices, and the glottis). The most common cause of noisy breathing in toddlers and young children is nasopharyngeal obstruction; in young infants, laryngomalacia is a leading cause. It is uncertain to what degree sounds from large intrathoracic airways contribute to the noise of breathing. Placing the stethoscope within the airstream in front of the mouth, one hears predominantly those sounds that are produced locally in the mouth and larynx. Noisy breathing is a common finding in patients with asthma and bronchitis and does not necessarily reflect intrathoracic airway pathology because the upper airways are also frequently affected in these patients.

To clarify the causes of noisy breathing, the parents or patient should describe their own perceptions of the noise: Does it occur during inspiration, expiration, or both? Is it just an exaggeration of the normal breath sound noise, or does it have musical qualities? Did an episode of choking precede the onset of noisy breathing? Is the abnormal sound more prominent during certain activities, such as exercise? At what times of day or night and in which body positions is it most noticeable? The physician should also inquire about associated cough, sputum production, and dyspnea.

Children may suffer from partial obstruction of the upper airways during sleep; complete obstruction, which is found in adult patients with sleep apnea, is less common. These children snore most nights, whereas normal children's snoring is largely confined to times of upper respiratory tract infection. Usually enlarged adenoids and tonsils cause the breathing disturbance. The physician should inquire about the typical signs and symptoms found in patients with increased work of breathing and abnormal sleep patterns at night (Box 1.1).

**Box 1.1**

## Clinical Symptoms in Children With Heavy Nocturnal Snoring

### Nighttime Manifestations

Profuse nocturnal sweating
Restless sleep
Abnormal movements during sleep
Special sleeping position
Enuresis

## Problems With Growth and Nutrition

Anorexia
Weight <3rd percentile
Nausea with or without vomiting

## Behavioral and Learning Problems

Hyperactivity
Aggression
Social withdrawal

## Minor Motor Problems

Lack of coordination
Clumsiness

## Other Manifestations

Frequent upper airway infections
Frequent morning headaches
Excessive daytime somnolence

In the older child and adolescent, the physician should first inspect the nasal passageways and proceed to an examination of the oropharynx before auscultation of the neck and thorax. The acoustic signs should be checked while the patient breathes first with the mouth open, and then closed. In younger children, examination of the nose and mouth is unpopular and often results in agitation and crying. It is better to start with auscultation before inspection in these children. Noisy breathers should be examined when they are sitting or standing upright and when they are lying down because upper airway geometry is position-dependent and may influence the respiratory sounds. The examiner should also note abnormal crying or speech in the patient, as this may point to laryngeal disease.

## Wheezing

Wheezing is a common respiratory symptom and refers to musical, adventitious lung sounds that are often heard by the patient as well as the physician. When asking the patient or the parents about wheezing, one should keep in mind that the use of lung sound terminology among nonprofessionals is not better standardized than it is among health care providers. The physician should inquire about musical, whistling noises during breathing; audiovisual recordings of wheezy young children may help caregivers to identify abnormal respiratory findings. The video examples show different presentations of two wheezy young children (Videos 1.1 and 1.2).

Most typically, wheezing is associated with hyperreactive airway disease, but any critical narrowing of the airways can produce wheezing. Box 1.2 lists conditions with wheeze and other sounds that may be confused with wheeze. The wheezing that is typical in asthma originates from oscillations of airways at many sites. On auscultation, one hears many different tones simultaneously, which is called *polyphonic wheezing*. Obstruction of a single airway can produce a single monophonic wheeze or, in the obstruction of extrathoracic airways, stridor. Both inspiratory and expiratory wheezes are present in the majority of asthmatic patients. The audible expiratory phase (expirium) is typically prolonged because of wheezing. Objectively measured expiratory time (expiration), however, is rarely prolonged except in very severe airway obstruction. Under these circumstances, air flow is minimal, and thus wheezing is absent. Respiration becomes ominously silent, and the patient may have carbon dioxide retention and cyanosis. In less severe cases, however, the proportion of inspiration and expiration occupied by wheezing correlates to some extent with the degree of air flow obstruction. Objective and reproducible wheeze quantification can be achieved by computer-assisted techniques, but in practice the quantification of wheezing severity is made by subjective assessment at the bedside.

**Box 1.2**

### Differential Diagnosis of Wheeze and Other Sounds That May Be Confused With Wheeze

**Upper airway disease**—adenotonsillar hypertrophy, rhinosinusitis, postnasal drip, subglottic stenosis, laryngomalacia, vocal cord paresis

**Congenital structural bronchial disease**—complete cartilage rings, cysts, webs

**Bronchial/tracheal compression**—vascular rings and sling, enlarged cardiac chamber, lymph nodes enlarged by tuberculosis or lymphoma

**Endobronchial disease**—foreign body, tumor

**Esophageal/swallowing problems**—reflux, incoordinate swallow, laryngeal cleft, or tracheoesophageal fistula

**Causes of pulmonary suppuration**—cystic fibrosis, primary ciliary dyskinesia, persistent bacterial bronchitis, any systemic immunodeficiency

**Miscellaneous**—bronchopulmonary dysplasia, congenital or acquired tracheomalacia, pulmonary edema

Reused with permission from Bush A, Nagakumar P. Preschool wheezing phenotypes. *EMJ*. 2016;1:93.

Wheezes are often high-pitched and will therefore attenuate during their passage through lung tissue, particularly if the lungs are hyperinflated. Auscultation over the neck may give a better impression of respiratory sounds and should be included as a part of the routine physical examination. Tracheal auscultation to determine if and when there is wheezing after methacholine inhalation challenge has been advocated instead of spirometry in young children being evaluated for bronchial hyperreactivity.

However, wheezing may be absent even if airways become significantly obstructed during bronchial provocation (Fig. 1.12). In our experience, wheezing heard at the chest but not necessarily at the trachea is very suggestive of airway narrowing and hyperresponsiveness. Listening to respiratory sounds over the neck may help to identify patients who are thought to be asthmatic but who generate the wheezing noises solely in the larynx. These are usually older children and adolescents with vocal cord dysfunction.

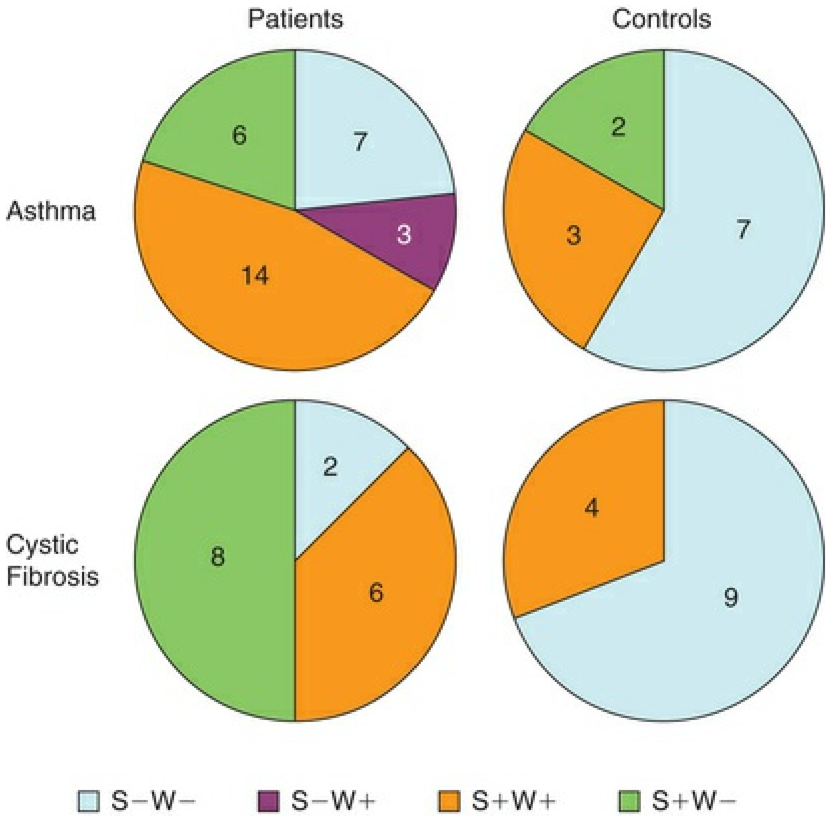

**FIG. 1.12** Summary of findings regarding wheeze as an indicator of significant flow obstruction during methacholine bronchial provocation in children. Negative responses (i.e., less than 20% decline in forced expiratory volume in 1 second at a dose of 8 mg/mL [spirometry] and no wheeze [acoustic monitoring]) are indicated by a minus sign, and positive responses are indicated by a plus sign. Note the low sensitivity of wheeze as an indicator of air flow obstruction, particularly in children with cystic fibrosis. *S,* Spirometry; *W,* wheezing. (Data from Sanchez I, Powell RE, Pasterkamp H. Wheezing and airflow obstruction during metacholine challenge in children with cystic fibrosis and in normal children. *Am Rev Respir Dis*.

1993;147:705, and Sanchez I, Avital A, Wong I, et al: Acoustic vs. spirometric assessment of bronchial responsiveness to methacholine in children. *Pediatr Pulmonol*. 1993;15:28.)

## Cyanosis

*Cyanosis* refers to a blue color of the skin and mucous membranes due to excessive concentrations of reduced hemoglobin in capillary blood. The oxygen content of capillary blood is assumed to be midway between that of arterial and that of venous blood. Areas with a high blood flow and a small arteriovenous oxygen difference (e.g., the tongue and mucous membranes) will not become cyanotic as readily as those with a low blood flow and a large arteriovenous oxygen difference (e.g., the skin of cold hands and feet). A distinction is therefore made between peripheral cyanosis (acrocyanosis), which is confined to the skin of the extremities, and central cyanosis, which includes the tongue and mucous membranes. Circumoral cyanosis is not an expression of central cyanosis and is rarely pathologic. The absolute concentration of reduced hemoglobin in the capillaries that is necessary to produce cyanosis is between 4 and 6 g/100 mL of blood. This level is usually present when the concentration of reduced hemoglobin in arterial blood exceeds 3 g/100 mL. Clinical cyanosis will occur at different levels of arterial oxygen saturation, depending on the amount of total hemoglobin (Fig. 1.13).

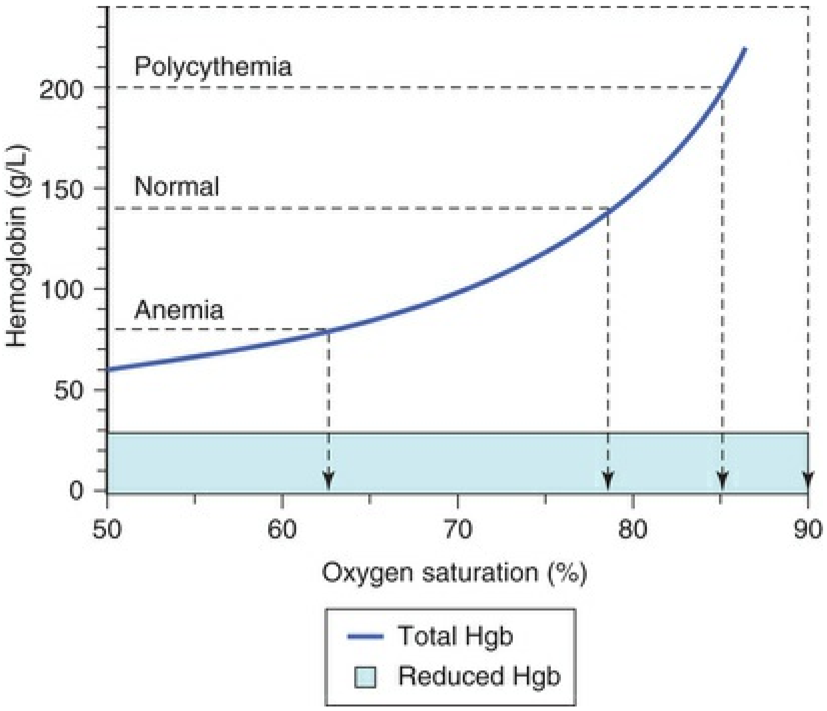

**FIG. 1.13** Cyanosis requires at least 30 g/L of reduced hemoglobin (Hgb) in arterial blood or 4–6 g/100 mL in capillary blood. The arterial oxygen saturation ($SaO_2$) at which cyanosis occurs is dependent on the amount of total Hgb. As illustrated, a child with 30 g/L of Hgb plus 110 g/L of oxyhemoglobin has an $SaO_2$ of 78%. In the anemic patient (i.e., total Hgb of 80 g/L with Hgb of 30 g/L), $SaO_2$ will drop much lower (to less than 65% in this example) before cyanosis occurs, whereas in the patient with polycythemia (i.e., total Hgb of 200 g/L), cyanosis appears at a higher $SaO_2$ (85%).

Physiologically, five mechanisms can cause arterial hemoglobin desaturation in the patient who breathes room air at normal altitude: (1) alveolar hypoventilation, (2) diffusion impairment, (3) right-to-left shunting, (4) mismatch of ventilation and perfusion, and (5) inadequate oxygen transport by hemoglobin. Clinically, diffusion impairment is of little importance as a single cause. Imbalance of ventilation and perfusion is by far the most common mechanism and is correctable by administration of 100% oxygen. The physician should therefore look for a change in cyanosis while the patient breathes oxygen.

Observer agreement regarding cyanosis was found to range from poor when assessing acrocyanosis to very good in the evaluation of young children with bronchiolitis. To minimize the variability of this finding, cyanosis is best observed under daylight and with the patient resting in a comfortably warm room. The distribution of cyanosis and the state of peripheral perfusion should be noted. Patients with decreased cardiac output and poor peripheral perfusion can be cyanotic despite normal arterial hemoglobin saturation. Some patients may become cyanotic only during exercise, a common response when restrictive lung disease reduces the pulmonary capillary bed and the transit time of erythrocytes becomes too short for full saturation to occur during episodes of increased cardiac output. Congenital heart disease in infants may lead to differential cyanosis, which affects only the lower part of the body (e.g., in patients with preductal coarctation of the aorta). Less commonly, only the upper part of the body is cyanotic (e.g., in patients with transposition of the great arteries in association with patent ductus arteriosus, and pulmonary to aortic shunting).

The clinical impression of cyanosis is usually confirmed by an arterial blood gas analysis or, more commonly, by pulse oximetry. Pulse oximetry, however, will not take into account the presence of abnormal hemoglobin. For example, in methemoglobinemia the oxygen-carrying capacity of blood is reduced and patients may appear lavender blue, but pulse oximetry may overestimate oxygen saturation in arterial blood ($SaO_2$). The blood of newborn infants, conversely, can be well saturated and not cyanotic at lower arterial oxygen tensions because of the different oxygen-binding curve of fetal hemoglobin. In the patient with hypoxemia who does not present with cyanosis (e.g., the anemic patient), the physician has to pay particular attention to other clinical signs and symptoms of hypoxia. These include tachypnea and tachycardia, exertional dyspnea, hypertension, headache, and behavioral changes. With more severe hypoxia, there may be visual disturbance, somnolence, hypotension, and ultimately coma. In addition, the patient may have an elevated level of carbon dioxide. Depending on how rapidly and to what extent the level of carbon dioxide has risen, the clinical signs of hypercarbia will largely reflect vascular dilatation. These signs include flushed, hot hands and feet; bounding pulses; confusion or drowsiness; muscular twitching; engorged retinal veins; and, in the most severe cases, papilledema and coma.

# Digital Clubbing

*Digital clubbing* refers to a focal enlargement of the connective tissue in the terminal phalanges of fingers and toes, most noticeably on their dorsal surfaces. This sign was first described by Hippocrates, and the term *Hippocratic fingers* is used by some to denote simple digital clubbing. The pathogenesis of clubbing is still not entirely clear. Vascular endothelial growth factor (VEGF) from the continued impaction of shunted megakaryocytes and platelets in the digital vasculature, potentiated by hypoxia, is considered to drive the cellular and stromal changes in clubbing. Enhanced VEGF expression is a common finding in various diseases that are associated with digital clubbing. Aside from VEGF, platelet-derived growth factor may contribute to the stromal changes, including the maturation of new microvessels.

Clubbing of the digits may be idiopathic, acquired, or hereditary. Cystic fibrosis, bronchiectasis, and empyema are the most common pulmonary causes of acquired digital clubbing in children. Clubbing is also seen infrequently in extrinsic allergic vasculitis, pulmonary arteriovenous malformations, bronchiolitis obliterans, sarcoidosis, and chronic asthma. Box 1.3 shows a list of nonpulmonary diseases associated with clubbing. A systemic disorder of bones, joints, and soft tissues known as *hypertrophic osteoarthropathy* (HOA) includes digital clubbing. Abnormal metabolism of prostaglandin $E_2$ has been suggested as the cause of digital clubbing in these patients. In the majority of cases, HOA is associated with bronchogenic carcinoma and other intrathoracic neoplasms, but the pediatrician may see HOA in patients with severe cystic fibrosis or chronic empyema and lung abscess. In addition to clubbing, these patients may have periosteal thickening; symmetric arthritis of ankles, knees, wrists, and elbows; neurovascular changes of hands and feet; and increased thickness of subcutaneous soft tissues in the distal portions of arms and legs. The primary idiopathic or hereditary form of HOA—pachydermoperiostosis—appears with prominent furrowing of the forehead and scalp. Approximately half of the reported cases have a positive family history. Genetic studies suggest an autosomal-dominant inheritance with variable expression and a predilection for males.

**Box 1.3**

### Nonpulmonary Diseases Associated With Clubbing

#### Cardiac

Cyanotic congenital heart disease
Subacute bacterial endocarditis
Chronic congestive heart failure

#### Hematologic

Thalassemia
Congenital methemoglobinemia (rare)

#### Gastrointestinal

Crohn disease
Ulcerative colitis
Chronic dysentery, sprue
Polyposis coli
Severe gastrointestinal hemorrhage
Small bowel lymphoma
Liver cirrhosis (including $\alpha_1$-antitrypsin deficiency)

#### Other

Thyroid deficiency (thyroid acropachy)
Chronic pyelonephritis (rare)
Toxic (e.g., arsenic, mercury, beryllium)
Lymphomatoid granulomatosis
Fabry disease
Raynaud disease, scleroderma

## Unilateral Clubbing

Vascular disorders (e.g., subclavian arterial aneurysm, brachial arteriovenous fistula)
Subluxation of shoulder
Median nerve injury
Local trauma

Digital clubbing is not only an important indicator of pulmonary disease but also may reflect the progression or resolution of the causative process. Pulmonary abscess and empyema may lead to digital clubbing over the course of only a few weeks. In this case, clubbing will resolve if effective treatment is instituted before connective tissue changes become fixed. Interestingly, even long-standing finger clubbing seems to resolve in patients after successful heart and lung transplantation. In patients with cystic fibrosis, progression of finger clubbing suggests a suboptimal control of chest infections. It is therefore useful to quantify the degree of digital clubbing. Measurements have focused on the hyponychial (Lovibond) angle and on the phalangeal depth ratio (Fig. 1.14). Computerized analysis from digital photographs has provided information on the distribution of the hyponychial angle in healthy subjects and in patients with various diseases. Almost 80% of adult patients with cystic fibrosis have a hyponychial angle greater than 190 degrees, the upper limit of normal.

**FIG. 1.14** (A) Normal and clubbed finger viewed in profile. (B) The normal finger demonstrates a distal phalangeal finger depth (DPD)/interphalangeal finger depth (IPD) ratio <1. The clubbed finger demonstrates a DPD/IPD ratio >1. (C) The normal finger on the left demonstrates a normal profile (abc) with angle less then 180°. The clubbed finger demonstrates a profile angle >180°. (D) Schamroth sign is demonstrated in the clubbed finger with the loss of diamond shape window in between finger beds that is demonstrated in the normal finger.

For routine clinical practice, the sign described by Schamroth, a cardiologist who developed finger clubbing during several attacks of infective endocarditis, is a most useful method of measuring finger clubbing (see Fig. 1.14). Another way is to place a plastic caliper with minimal pressure over the interphalangeal joint. If it is easy to slide the caliper from this joint across the nail fold, the distal phalangeal diameter to interphalangeal diameter ratio must be less than 1, and the patient has no clubbing.

## Cardiovascular Signs

Pulmonary heart disease, or *cor pulmonale,* is a consequence of acute or chronic pulmonary hypertension and appears as right ventricular enlargement. The progression of chronic cor pulmonale to ultimate right ventricular failure is accompanied by certain physical signs. Initially, the right ventricular systolic pressure and muscle mass increase as pulmonary artery pressure rises. During this stage, cardiac auscultation may be normal or may reveal an increased pulmonary component of the second heart sound, caused by an increase in diastolic pulmonary arterial pressure. The physician should look for a parasternal right ventricular heave. As pulmonary hypertension progresses, there is an increase in right ventricular end-diastolic volume. Dilation of the main pulmonary artery and right ventricular outflow tract lead to systolic pulmonary ejection clicks and murmurs. Diastolic murmurs appear when pulmonary or tricuspid valves or both become insufficient. Third and fourth heart sounds at the left lower sternal border are signs of decreased right ventricular compliance. Most of these right-sided cardiovascular findings are accentuated during inspiration, which augments venous return. Finally, cardiac output falls while end-diastolic pressure and volume increase further in the failing right ventricle.

Clinical findings at this stage include hepatic engorgement, jugular venous distention, and peripheral edema. Occasionally, there may be cyanosis and intracardiac right-to-left shunting through a patent foramen ovale. The physician should exclude the possibility of congenital cardiac defects or acquired left-sided heart disease before making the diagnosis of cor pulmonale. Hyperinflation of the lungs should be taken into account as a cause of the attenuation of cardiovascular sounds and the lowering of the subcostal liver margin, which may be misinterpreted as hepatic enlargement.

Complete assessment of the cardiovascular system includes careful auscultation, and palpation of the pulse to detect cardiac arrhythmia. This problem is common in patients with chronic lung disease and may appear as sinus or paroxysmal supraventricular tachycardia, atrial premature contractions, or ventricular ectopic beats. Causes include hypoxemia, acid-base imbalance, and enlargement of the right heart; effects of common drugs such as aminophylline, beta sympathomimetics, or diuretics should not be overlooked.

During quiet spontaneous respiration, there is a phasic variation of arterial blood pressure. The widening of this normal respiratory variation is known as *pulsus paradoxus.* Increased respiratory resistance may exaggerate the normal inspiratory-expiratory difference in left ventricular stroke volume. This is mediated by effects of intrathoracic pressures on ventricular preload. Clinically, pulsus paradoxus is first assessed by palpation of the radial pulse and then it is measured at the brachial artery with a sphygmomanometer as the difference in systolic pressure between inspiration and expiration. The pressure cuff is deflated from above systolic level, and the highest pressure during expiration at which systolic pulse sounds are heard is recorded. Similarly, the highest pressure at which every pulse is just audible throughout inspiration is also noted. In general, a drop of greater than 10 mm Hg during inspiration is taken as clinically significant, but only a severe paradox of greater than 24 mm Hg is a reliable indicator of severe asthma. The poor correlation between pulsus paradoxus and objective measurements of air flow obstruction may be explained by other factors that affect pleural pressure swings (e.g., the degree of pulmonary hyperinflation and the air flow rate). Furthermore, the accurate measurement of pulsus paradoxus is a challenge in tachypneic, tachycardic, and uncooperative young children. A work group of the British Thoracic Society Standards of Care Committee found pulsus paradoxus to be absent in one-third of patients with the most severe obstruction. In contrast to North American practice guidelines, it was therefore recommended that pulsus paradoxus be abandoned as an indicator of severity of asthma attack. In children, wheeze seems to be the clinical parameter of respiratory severity scores that correlates best with pulsus paradoxus, most likely because wheeze requires critical intrathoracic pressures. The application of pulse oximetry to view dynamic changes in the area under the plethysmographic waveform in relation to pulsus paradoxus shows some promise in improving the diagnostic value of this clinical sign.

## Exercise Limitation and Dyspnea

Reduced performance on physical exertion is another frequent cause for consultation with a pediatric pulmonologist. Frequently this will be in the context of a child who has difficulty keeping up with his peers and may have many other associated symptoms such as coughing and wheezing.

Dyspnea refers to the subjective perception of difficulty breathing. While there are well-established scoring systems for dyspnea in adult subjects, there are few validated assessment tools for children and adolescents. Pictorial scales may help in documenting and following dyspnea in the young patient (Fig. 1.15).

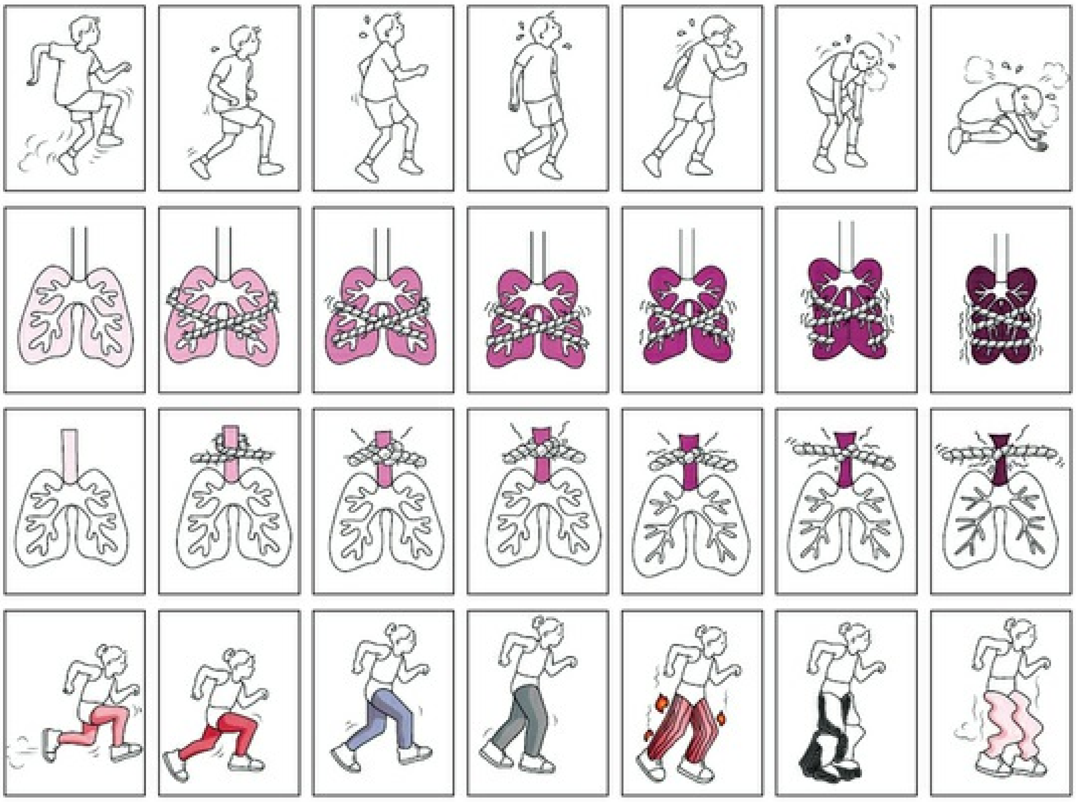

**FIG. 1.15** Pictorial scales of perceived breathlessness. These Dalhousie Dyspnea Scales have interval scale characteristics that allow measurements of breathlessness in children more than 8 years old. (McGrath PJ, Pianosi PT, Unruh AM, et al. Dalhousie dyspnea scales: construct and content validity of pictorial scales for measuring dyspnea. *BMC Pediatr*. 2005;5:1)

The most common cause for exertional dyspnea appears to be physiologic limitation. This includes children and adolescents who are deconditioned, have a sedentary lifestyle, and is often associated with obesity. The symptoms typically worsen with increasing exertion and improve rapidly with rest. Although chest pain may be present, cough and wheeze are rarely associated with this. This may also occur in adolescents with normal or above-average cardiovascular conditioning. Often these are motivated children who are unable to keep up with other more "elite" athletes. This can also be seen in children who previously were competing at a high level but on entering adolescence there begins an increasing separation from the elite athletes and other children. They may start to no longer keep up with other children at their level of competition and thereby disappoint not only their own expectations but also those of their parents. Vocal cord dysfunction may be seen in this population as well. Symptoms of stridor and voice changes may be present. However, some children may have symptoms difficult to distinguish from true asthma during these episodes.

Asthma and exercise-induced bronchospasm are a common cause of dyspnea and these are frequently associated with coughing, wheezing, and dyspnea or chest pain. The symptoms may continue to worsen after the child stops the exertion. This can often be the presenting feature of poorly controlled asthma. The more detailed history will elucidate symptoms of persistent asthma, for example, nocturnal coughing or prolonged cough, wheeze with viral illnesses, and an atopic history. There is also evidence that exercise-induced bronchospasm is more common in elite athletes, especially performing endurance and cold weather sports.

Cardiac causes for exertional dyspnea in children are quite rare. A history of congenital or acquired heart disease should raise suspicion. Other cardiac etiologies accounting for dyspnea may include conduction abnormalities, pulmonary hypertension, congestive heart failure, valvular disease, and myocarditis. Associated but nonspecific symptoms may include palpitations, diaphoresis, and severe chest pain.

Exertional limitation can also be seen with chronic lung diseases, for example, cystic fibrosis or bronchopulmonary dysplasia. Airway abnormalities, for example, tracheomalacia or vascular ring abnormalities are also frequently associated with exertional limitation. Finally, children with myopathies and other neuromuscular disorders may have exercise intolerance, not associated with dyspnea, as an early symptom. A careful exploration of triggers leading to the limitation and of other signs of muscle weakness is helpful.

## Chest Pain

Chest pain is relatively common in older children and adolescents but may also be present in younger children. The occurrence rate in an emergency department approaches 2.5 per 1000 patient visits, and chest pain accounts for an estimated 650,000 physician visits of patients between 10 and 21 years of age annually in the United States. Chest pain in children is most often benign and self-limited. Typical origins are musculoskeletal problems and idiopathic, dysfunctional, and psychogenic causes (Box 1.4). Younger children have underlying cardiorespiratory problems more frequently, whereas children older than 12 years of age are more likely to have a psychogenic or musculoskeletal cause.

**Box 1.4**

## Causes of Chest Pain in Children

### Thorax

Costochondritis
Tietze syndrome
Muscular disease
Precordial catch
Trauma
Connective tissue disorders
Xiphoid-cartilage syndrome
Rib tip syndrome
Leukemia
Herpes zoster
Breast development or disease (e.g., gynecomastia, mastitis)

### Lungs, Pleura, and Diaphragm

Asthma
Cystic fibrosis
Infection (e.g., bronchitis, pneumonia, epidemic pleurodynia)
Inhalation of irritants (e.g., chemical pneumonitis, smoking)
Stitch (associated with exercise)
Foreign body
Pneumothorax
Pleural disease (e.g., pleurisy, effusion)
Diaphragmatic irritation (e.g., subphrenic abscess, gastric

distention)
Sickle cell anemia

## Cardiovascular System

Structural lesions (e.g., mitral valve prolapse, idiopathic hypertrophic subaortic stenosis [IHSS], coronary disease)
Acquired cardiac disease (e.g., carditis, arteritis, tumor involvement)
Arrhythmia

## Esophagus

Gastroesophageal reflux
Foreign body
Achalasia

## Vertebral Column

Deformities (e.g., scoliosis)
Vertebral collapse

## Psychogenic Causes

Anxiety
Hyperventilation
Unresolved grief
Identification with another person suffering chest pain

The history is most important in the assessment of these patients who usually have few physical findings and rarely any laboratory data of diagnostic value. The physician should recognize a clinical profile suggestive of psychogenic pain but should also keep in mind that psychogenic and organic causes are not mutually exclusive. A substantial number of patients have a family history of chest pain. Parents of younger children should explain how they know that their child is in pain. It is important to determine whether sleep is affected, because organic pain is more likely than psychogenic pain to awaken the patient or to prevent the child from falling asleep. A close inspection and careful palpation of the chest and abdomen are essential. Common abnormal findings include chest wall tenderness, fever, or both. The physician should use pressure on the stethoscope to elicit local tenderness while the patient is distracted by the auscultation.

In general, the presence of systemic signs such as weight loss, anorexia, or syncopal attacks will direct the attention to organic causes of chest pain in children. Diffuse, deep, substernal, and epigastric pains are likely to be visceral, originating in the thorax if the pain affects dermatomes T1 to T4 and in the diaphragm or abdomen if it affects dermatomes T5 to T8.

The duration of symptoms may be an indicator. Acute, short-lasting pain is more likely to be organic and localized; sharp, and superficial pains suggest an origin in the chest wall. Costochondritis is associated with pain localized to a specific area of the chest that can be reproduced on palpation. There are no associated inflammatory signs and it often follows episodes of severe coughing or chest trauma. Conversely, Tietze syndrome, also known as costochondral junction syndrome, has similar symptoms to costochondritis but is also associated with signs of inflammation such as warmth and redness over the affected joint. It often has a postinfectious etiology. Precordial Catch Syndrome presents with a localized sudden onset that will last several seconds to several minutes followed by complete resolution. It occurs more commonly on the left side. Theorized etiologies include a pinching of the nerve and local muscle spasms. Recent trauma may also lead to chest pain through fractured ribs, muscle bruising, and/or a pneumothorax. Slipping rib syndrome involves irritation of the intercostal nerve slipping under an adjacent floating rib (8th, 9th, and 10th). There is often a history of clicking of the rib. A hooking maneuver in which the physician places his fingers under the lower costal margin at the mid axillary line and lifts anteriorly, reproducing a “click” and the pain, is diagnostic.

Pain that is longer in duration and vague or changing in description is more likely psychogenic in nature. Psychogenic pain may be worse with stressful events and associated symptoms such as headaches and abdominal pains. A detailed social history including family and school situations is important. A history of hyperventilating and/or dizziness of feeling light headed may suggest disordered breathing and/or anxiety disorders.

Respiratory causes of chest pain are also frequent. Asthma, pneumonia, pleural effusions, and pneumothoraxes can all present with chest pain, although they often have other associated symptoms. Cardiac causes of pain are rare. However, in up to 50% of adolescents seeking medical attention for chest pain, the major worry for the families is a possible cardiac etiology. Pericarditis will be associated with fever and a friction rub. The chest pain is more constant and radiates to the left shoulder and it worsens with deep breathing and lying down. Arrhythmias may be associated with other symptoms such as palpitations, dyspnea, nausea, and fatigue. Cardiac murmurs with or without a midsystolic click may be found in patients with mitral valve prolapse, but this condition is rarely associated with chest pain, at least in children. More commonly, there are noncardiac causes of chest pain in children with mitral valve prolapse (e.g., orthopedic or gastroesophageal disorders).

Pulmonary emboli frequently have a sudden onset of pain and associated dyspnea and tachycardia. However, associated symptoms in children may be minimal even in the presence of a large embolus. A recent history of starting an oral contraceptive should raise the suspicion.

Gastrointestinal causes are also rare causes of chest pain in children. GER with or without esophagitis may produce retrosternal pain and is often associated with eating. Epigastric pain may be indicative of peptic ulcers. Diaphragmatic transmitted pain may also occur from abdominal pathologies such as pancreatitis.

Idiopathic chest pain is a common final diagnosis in many reported prospective and retrospective series in which there is no final diagnosis identified.

## Conclusion

In pediatric respiratory medicine, the most common clinical presentation is that of a child who coughs or wheezes, or both. Depending on the geographic location, the information gathered from the history and physical examination will carry different weights in the initial diagnostic approach. Pneumonia kills more children than any other disease. In countries with high morbidity and mortality from lower respiratory tract infections, assessment of children who cough will therefore initially focus on the possibility of pneumonia. A constellation of physical findings—particularly fever, tachypnea and retractions, nasal flaring in infants younger than 1 year of age, and history of poor feeding—increase the likelihood that the child has pneumonia. Any single clinical finding by itself, however, is not useful as a predictor.

Concurrent wheezing is more common in viral than in bacterial infections and a history of preceding similar events and of improvement after bronchodilator inhalation can lead to different first steps in treatment. In most Western countries, the likelihood of bacterial pneumonia in a child who presents with cough with or without wheeze is lower, while asthma or prolonged symptoms after viral infections of the lower respiratory tract are common. Recurrent wheezing is particularly prevalent; up to 40% of children will present with wheezing during their first year of life but less than one-third of these will have asthma when they reach school age. If the parents of a child younger than 3 years of age who only wheezes with colds do not have asthma or eczema and if the child does not have allergic rhinitis, the negative predictive value of this history is close to 90% with regard to having asthma by the age of school entry.

At school age, functional respiratory assessment by spirometry is generally possible. It is therefore surprising that only a minority of children with asthma symptoms will have lung functions tests. It would be comforting if this could be explained by a superiority of history and physical examination to detect abnormalities. However, the physician should recognize limitations of any component in the diagnostic workup. Only then can the value of a detailed history and a skillfully performed physical examination be appreciated.

# Molecular Determinants of Lung Morphogenesis

*Daniel T. Swarr MD, Susan E. Wert PhD, Jeffrey A. Whitsett MD*

## Introduction

The adult human lung consists of a gas exchange area of approximately 100 $m^2$ that provides oxygen delivery and carbon dioxide removal required for cellular metabolism. In evolutionary terms, the lung represents a relatively late phylogenetic solution for the efficient gas exchange needed for terrestrial survival of organisms of increasing size, an observation that may account for the similarity of lung structure in vertebrates.[1] The respiratory system consists of mechanical bellows and conducting tubules that bring inhaled gases to a large gas exchange surface that is highly vascularized. Alveolar epithelial cells (AECs) come into close apposition to pulmonary capillaries, providing efficient transport of gases from the alveolar space to the pulmonary circulation. The delivery of external gases to pulmonary tissue necessitates a complex organ system that (1) keeps the airway free of pathogens and debris, (2) maintains humidification of alveolar gases and precise hydration of the epithelial cell surface, (3) reduces collapsing forces inherent at air-liquid interfaces within the air spaces of the lung, and (4) supplies and regulates pulmonary blood flow to exchange oxygen and carbon dioxide efficiently. This chapter provides a framework for understanding the molecular mechanisms that lead to the formation of the mammalian lung, focusing attention to processes contributing to cell proliferation and differentiation involved in organogenesis and postnatal respiratory adaptation. Where possible, the pathogenesis of congenital or postnatal lung disease is considered in the context of the molecular determinants of pulmonary morphogenesis and function.

# Organogenesis of the Lung

## Formation of the Basic Body Plan

Events critical to organogenesis of the lung begin with formation of anterior-posterior (A-P), dorsal-ventral, and left-right axes in the early embryo, which, in turn, specifies the basic body plan of each organism. The formation of these axes is determined by genes that control cellular proliferation and differentiation and depends on complex interactions among many cell types. The fundamental principles determining embryonic organization have been elucidated in simpler model organisms (e.g., amphibians, fruit flies, sea urchins, snails, worms, and zebra fish) and applied to increasingly complex organisms (e.g., mouse and human), as the genes determining axial segmentation, organ formation, cellular proliferation and differentiation have been identified. Segmentation and organ formation in the embryo are profoundly influenced by sets of master control genes that include various classes of transcription factors. Critical to formation of the axial body plan are the homeotic, or HOX, genes.[2] HOX genes are arrayed in clearly defined spatial patterns within clusters on several chromosomes. HOX gene expression in the developing embryo is determined in part by the position of the individual genes within these gene clusters, which are aligned along the chromosome in the same order as they are expressed along the A–P axis. Complex organisms have more individual HOX genes within each locus and have more HOX gene loci than simpler organisms. In addition, HOX genes encode nuclear proteins that bind to DNA via a highly conserved homeodomain motif that modulates the transcription of specific sets of target genes. The temporal and spatial expression of these nuclear transcription factors, in turn, control the expression of other HOX genes and their transcriptional targets during morphogenesis and cytodifferentiation.[3,4] Expression of HOX genes influences many downstream genes, such as transcription factors, growth factors, signaling peptides, and cell adhesion molecules,[4] which are critical to the formation of the primitive endoderm from which the respiratory epithelium is derived.[5]

## Specification of the Foregut Endoderm

The primitive endoderm develops very early in the process of embryogenesis, that is, during gastrulation and prior to formation of the intraembryonic mesoderm, ectoderm, and the notochord, which occurs in humans at 3 weeks postconception (WPC).[6] Specification of the definitive endoderm and the primitive foregut requires the activity of a number of nuclear transcription factors that regulate gene expression in the embryo, including forkhead box A2 (FOXA2) (also known as hepatocyte nuclear factor 3-beta, or HNF-3β), GATA-binding protein 6 (GATA6), sex-determining region Y (***S***RY)-related high mobility group (HMG)-b***ox*** (SOX) 17 (SOX17), SOX2, β-catenin, retinoic acid receptors (RAR), and members of the T-box family of transcription factors.[7–15] Genetic ablation of these transcription factors disrupts formation of the primitive foregut endoderm and its developmental derivatives, including the trachea and the lung.[11,12,16–20] Some of these transcription factors are also expressed in the respiratory epithelium later in development when they play important roles in the regulation of cell differentiation and organ function.[8,21–25]

## Lung Morphogenesis

Lung morphogenesis is initiated during the embryonic period of fetal development (3–4 WPC in the human) with the formation of a small saccular outgrowth of the ventral wall of the foregut endoderm, a process that is induced by expression of WNT2/2b and fibroblast growth factor (FGF) 10, in the adjacent splanchnic mesoderm (Fig. 2.1).[26–28] After the main bronchial tubes form the lung tubules, they undergo branching morphogenesis to create the highly arborized, stereotypical patterns of airway segmentations.[29] This region of the ventral foregut endoderm is delineated by epithelial cells expressing the homeobox gene, NKX2-1 (also known as thyroid transcription factor-1 [TTF1]), which is the earliest known marker of the prospective respiratory epithelium.[30] Thereafter, lung development can be subdivided into five distinct periods of morphogenesis based on the morphologic characteristics of the tissue (Table 2.1; Fig. 2.2). While the timing of this process is highly species specific, the anatomic events underlying lung morphogenesis are shared by all mammalian species. Details of human lung development are described in the following sections, as well as in several published reviews.[31–37]

**FIG. 2.1** Foregut patterning and lung bud morphogenesis. (A) Prior to outgrowth of the lung bud, the foregut consists of a single undivided tube of epithelium surrounded by mesenchyme *(orange).* Wnts and fibroblast growth factors (FGFs) secreted by the mesenchyme act to pattern the nascent lung, marked by expression of Nkx2-1 *(green).* Posteriorly, the future esophagus is marked by Sox2 expression *(blue)* and receives patterning signals from the notochord, such as the bone morphogenic protein (BMP) antagonist Noggin. (B) A complex series of signals involving Wnts, Fgfs, BMPs, and retinoic acid pathways continue

to pattern the lung and direct bud outgrowth during the pseudoglandular stage. Fgf10 produced in the distal mesoderm *(green)* acts on the epithelium *(purple)* to promote cell proliferation and morphogenesis. Negative feedback in provided on Fgf10 by retinoic acid (RA), Sprouty-1 and -2 (Spry1,2), and Sonic hedgehog (SHH). Wnt signaling continues to promote growth of both the epithelium and mesenchyme, and interacts with several other signaling pathways, including BMP4.

## Table 2.1

### Morphogenetic Periods of Human Lung Development

| **Period** | **Age (WPC)** | **Structural Events** |
|---|---|---|
| Embryonic | 3–6 | Lung buds; trachea, main stem, lobar, and segmental bronchi; trachea and esophagus separate |
| Pseudoglandular | 6–17 | Subsegmental bronchi, terminal bronchioles, and acinar tubules; mucous glands, cartilage, and smooth muscle |
| Canicular | 16–26 | Respiratory bronchioles, acinus formation and vascularization; type I and II AEC differentiation |
| Saccular | 26–36 | Dilation and subdivision of alveolar saccules, increase of gas-exchange surface area, and surfactant synthesis |
| Alveolar | 36—maturity | Further growth and alveolarization of lung; increase of gas-exchange area and maturation of alveolar capillary network; increased surfactant synthesis |

*AEC,* Alveolar epithelial cells; *WPC,* weeks postconception.

26-36 WPC
Alveolar
36 WPC to adolescence

**FIG. 2.2** Major stages of lung development. Bronchi, bronchioles, and acinar tubules are formed by the process of branching morphogenesis during the pseudoglandular stage of lung development (6–17 WPC). Formation of the capillary bed and dilation/expansion of the acinar structures is initiated during the canalicular stage of lung development (16–26 WPC). Growth and subdivision of the terminal saccules and alveoli continue until early adolescence by septation of the distal respiratory structures to form additional alveoli. Cytodifferentiation of mature bronchial epithelial cells (secretory and ciliated cells) is initiated in the proximal conducting airways during the canalicular stage of lung development, while complete cytodifferentiation in the distal airways (secretory and ciliated cells) and alveoli (type I and type II alveolar epithelial cells [AECs]) takes place later during the saccular (26–36 WPC) and alveolar (36 WPC to adolescence) stages of lung development. The alveolar stage of lung development extends into the postnatal period, during which millions of additional alveoli are formed, and maturation of the microvasculature, or air-blood barrier, takes place, greatly increasing the surface area available for gas exchange.

## The Embryonic Period (3–7 Weeks Postconception)

Relatively undifferentiated epithelial cells of the primitive foregut endoderm form tubules that invade the surrounding splanchnic mesoderm and undergo branching morphogenesis. This process requires highly controlled epithelial cell proliferation and migration to direct dichotomous branching of the respiratory tubules, which form the main-stem, lobar, and segmental bronchi of the primitive lung (see Table 2.1; Fig. 2.2). The respiratory epithelium remains relatively undifferentiated and is lined by columnar epithelium during this process. Proximally, the trachea and esophagus also separate into two distinct structures during this period. Experimental removal of mesenchymal tissue from the embryonic endoderm at this time arrests branching morphogenesis, demonstrating the critical role of mesenchyme in the formation of the respiratory tract.[38] Interactions between epithelial and mesenchymal cells are mediated by a variety of signaling pathways that involve the binding of secreted peptides and extracellular matrix proteins to their respective cell surface receptors, which regulates gene transcription in differentiating lung cells. These epithelial-mesenchymal interactions involve both autocrine and paracrine signaling pathways that are critical for lung morphogenesis (Fig. 2.3). Paracrine signaling pathways important for initial formation of the lung bud, as well as expansion and branching of the primitive respiratory tubules, include (1) FGF10/FGFR2, (2) sonic hedgehog (SHH/PTCH1), (3) transforming growth factor-beta (TGFβ/TGFβR2), (4) bone morphogenic protein B (BMP4/BMPR1b), (5) retinoic acid (RA/RARα, β, γ), (6) WNT (WNT2/2b, 7b, 5a and R-spondin with their receptors Frizzled and LRP5/6), and (7) the β-catenin signaling pathways.[8,22,23,25,34,38–41] Nuclear transcription factors that are active in the primitive respiratory epithelium during this period include NKX2-1, FOXA2, GATA6, and SOX2. Likewise, transcription factors active in the mesenchyme at this time include (1) the HOX family of transcription factors (HOXA5, B3, B4); (2) the SMAD family of transcription factors (SMAD2, 3, 4), downstream transducers of the TGFβ/BMP signaling pathway; (3) the LEF/TCF family of transcription factors, downstream transducers of β-catenin, (4) the GLI-KRUPPEL family of transcription factors (GLI1, 2, 3), downstream transducers of SHH signaling; (5) the hedgehog-interacting protein, HHIP1, that binds SHH; and (6) FOXF1, another SHH target. Disruption of many of these transcription factors and signaling pathways in experimental animals causes impaired morphogenesis, resulting in laryngotracheal malformations, tracheoesophageal fistulas, esophageal and tracheal stenosis, esophageal atresia, defects in pulmonary lobe formation, pulmonary hypoplasia, or pulmonary ageneisis.[8,22,23,25,37–41]

**FIG. 2.3** Examples of reciprocal signaling during lung morphogenesis. Examples of reciprocal signaling during lung morphogenesis. Paracrine and autocrine interactions between the respiratory epithelium and the adjacent mesenchyme are mediated by signaling peptides and their respective receptors, influencing cellular behaviors (e.g., proliferation, migration, apoptosis, extracellular matrix deposition) that are critical to lung formation. For example, fibroblast growth factor (FGF)10 is secreted by mesenchymal cells and binds to its receptor, FGFR2, on the surface of epithelial cells (paracrine signaling). Sonic hedgehog (SHH) is secreted by epithelial cells and binds to its receptor, PTCH1, on mesenchymal cells

(paracrine signaling), while HHIP1 is upregulated by SHH in mesenchymal cells, secreted, and binds back to receptors on cells in the mesenchyme (autocrine signaling). Binding of SHH to mesenchymal cells activates the transcription factors, GLI1, GLI2, and GLI3, which, in turn, inhibit the expression of FGF10 (negative feedback loop). In contrast, the binding of HHIP1 to mesenchymal cells attenuates or limits the ability of SHH to inhibit FGF10 signaling. Together, these complex, interacting, signaling pathways control branching morphogenesis of the lung, differentially influencing bronchial tubule elongation (growth), arrest, and subdivision (lateral buds) into new tubules. *BMP,* Bone morphogenic protein; *TGF-β,* transforming growth factor-β; *VEGF,* vascular endothelial growth factor.

Although formation of the larger, more proximal, conducting airways, including segmental and subsegmental bronchi, is completed by 6 WPC, both epithelial and mesenchymal cells of the embryonic lung remain relatively undifferentiated. At this stage, trachea and bronchial tubules lack underlying cartilage, smooth muscle, or nerves; and the pulmonary and bronchial vessels are not well developed. Vascular connections with the right and left atria are established by a common cardiopulmonary vascular progenitor at the end of this period (6–7 WPC), creating the primitive pulmonary vascular bed.[33,42] Human developmental anomalies occurring during this period of morphogenesis include laryngeal, tracheal, esophageal, and bronchial atresia; tracheoesophageal and bronchoesophageal fistulas; tracheal and bronchial stenosis; bronchogenic cysts; ectopic lobes; extrapulmonary sequestration; and pulmonary agenesis.[37,43] Some of these congenital anomalies are associated with documented mutations in the genes involved in early lung development, such as GLI3 (tracheoesophageal fistula found in Pallister-Hall syndrome), FGFR2 (various laryngeal, esophageal, tracheal, and pulmonary anomalies found in Pfeiffer, Apert, or Crouzon syndromes), and SOX2 (esophageal atresia and tracheoesophageal fistula found in anophthalmia-esophageal-genital, or AEG, syndrome).[37,43]

## The Pseudoglandular Period (6–17 Weeks Postconception)

The pseudoglandular stage is so named because of the distinct glandular appearance of the lung from 6 to 17 WPC. During this period, the lung consists primarily of epithelial tubules surrounded by a relatively thick mesenchyme. Branching of the airways continues with formation of the terminal bronchioles and primitive acinar structures, which is completed by the end of this period (see Table 2.1; Fig. 2.2). During the pseudoglandular period, epithelial cell differentiation is increasingly apparent; and deposition of cellular glycogen and expression of genes expressed selectively in the distal respiratory epithelium are initiated. The surfactant proteins, SFTPB and SFTPC, are first detected in primitive type II AECs at 12–14 weeks of gestation.[44,45] Tracheobronchial glands begin to form in the proximal conducting airways; and the airway epithelium is increasingly complex, with basal, mucous, ciliated, and nonciliated secretory cells being detected.[35,36] Neuroendocrine cells, often forming clusters of cells, termed *neuroepithelial bodies*, express a variety of neuropeptides and transmitters (e.g., bombesin, calcitonin-related peptide, serotonin, and others) and are increasingly apparent along the bronchial and bronchiolar epithelium.[46–48] Smooth muscle and cartilage are now observed adjacent to the conducting airways,[49] and the pulmonary vascular system develops in close relationship to the bronchial and bronchiolar tubules between 9 and 12 WPC when smooth muscle actin and myosin can be detected in these vascular structures.[33]

During this period, FGF10, BMP4, TGFβ, β-catenin, and the WNT signaling pathways continue to be important for branching morphogenesis, along with several other signaling peptides and growth factors, including members of the (1) FGF family (FGF1, FGF2, FGF7, FGF9, FGF18); (2) TGFβ family, such as the SPROUTYs (SPRY2, SPRY4), which antagonizes and limits FGF10 signaling, and LEFTY/NODAL, which regulates left-right patterning; (3) epithelial growth factor (EGF) and transforming growth factor alpha (TGF$\alpha$) family, which stimulate cell proliferation and cytodifferentiation; (4) insulin growth factor (IGFI, IGFII) family, which facilitates signaling of other growth factors; (5) platelet derived growth factor (PDGFA, PDGFB) family, whose members are mitogens and chemoattractants for mesenchymal cells; and (6) vascular endothelial growth factor (VEGFA, VEGFC) family, which regulates vascular and lymphatic growth and patterning.[8,22,23,25,34,37,38,40] Many of the nuclear transcription factors that were active during the embryonic period of morphogenesis continue to be important for lung development. Additional transcriptional factors important for specification and differentiation of the primitive lymphatic vessels in the mesenchyme at this time include (1) SOX18, (2) the paired-related homeobox gene, PRX1, (3) the divergent homeobox gene, HEX, and (4) the homeobox gene, PROX1.[34,37]

A variety of congenital defects may arise during the pseudoglandular stage of lung development, including tracheomalacia and bronchomalacia, intralobar bronchopulmonary sequestration, congenital pulmonary airway malformations (formerly cystic adenomatoid malformations), acinar aplasia or dysplasia, alveolar capillary dysplasia with or without misalignment of the pulmonary veins, congenital pulmonary lymphangiectasia, and other pulmonary vascular malformations.[37] The pleuroperitoneal cavity also closes early in the pseudoglandular period. Failure to close the pleural cavity, often accompanied by herniation of the abdominal contents into the chest (congenital diaphragmatic hernia), may cause pulmonary hypoplasia.

## The Canalicular Period (16–26 Weeks Postconception)

The canalicular period is characterized by further growth and subdivision of the acinar tubules, rapid expansion of the pulmonary capillary bed, thinning of the pulmonary mesenchyme, and formation of the alveolar-capillary membrane (see Table 2.1; Fig. 2.2). By the end of this period, the terminal bronchioles have divided to form two or more respiratory bronchioles, and each of these has divided into multiple acinar tubules, forming the primitive pulmonary acini. Epithelial cell differentiation becomes increasingly complex and is especially apparent in the distal regions of the lung parenchyma. Bronchiolar cells express differentiated features, such as cilia, and secretory cells synthesize cell-specific secretory proteins, such as mucin and secretoglobin

1A1 (SCGB1A1).[45,50] Cells lining the distal tubules assume cuboidal shapes and express increasing amounts of surfactant phospholipids and the associated surfactant proteins, surfactant protein A (SFTPA), SFTPB, and SFTPC.[44,51] Lamellar bodies, composed of surfactant phospholipids and proteins, are seen in association with rich glycogen stores in the cuboidal pretype II AECs that line the distal acinar tubules.[52] Some cells of the acinar tubules become squamous, acquiring features of typical type I AECs. Capillaries surround the distal acinar tubules and establish contact with the adjacent epithelium to form the primitive alveolar-capillary membrane, which ultimately forms the gas exchange region of the mature lung. By the end of the canalicular period in the human infant (26–28 WPC), gas exchange can be supported after birth, especially when surfactant is provided by administration of exogenous surfactant.[53] Surfactant synthesis and parenchymal thinning can be accelerated by glucocorticoids at this time, which is why they are administered to mothers to prevent respiratory distress syndrome (RDS) after premature birth.[54,55] Abnormalities of lung development that occur during the canalicular period include congenital alveolar dysplasia, alveolar capillary dysplasia, and pulmonary hypoplasia, and the latter is caused by (1) diaphragmatic hernia, (2) compression due to thoracic or abdominal masses, (3) prolonged rupture of membranes causing oligohydramnios, or (5) renal agenesis, in which amniotic fluid production is impaired. While postnatal gas exchange can be supported late in the canalicular stage, infants born during this period generally suffer severe complications related to decreased pulmonary surfactant, which causes RDS and bronchopulmonary dysplasia, and the latter is a complication secondary to the intensive care therapy and increasing survival of very preterm infants.[56,57]

## The Saccular (26–36 Weeks Postconception) and Alveolar Periods (36 Weeks Postconception Through Adolescence)

These periods of lung development are characterized by increased thinning of the respiratory epithelium and pulmonary mesenchyme, further growth and expansion of the pulmonary acini, and development of the distal alveolar capillary network (see Table 2.1; Fig. 2.2). Maturation of type II AECs occurs in association with increased synthesis of surfactant phospholipids,[58] the surfactant proteins, SFTPA, SFTPB, and SFTPC,[53,59] and the adenosine triphosphate (ATP)-binding cassette transporter, ABCA3, a phospholipid transporter important for lamellar body biogenesis.[60] Squamous type I AECs line an ever-increasing proportion of the surface area of the distal lung. Adjacent interstitial capillaries become closely associated with the squamous type I AECs, decreasing the diffusion distance for oxygen and carbon dioxide between the alveolar space and capillary bed. Basal laminae of the epithelium and endothelium fuse to form the thin-walled alveolar-capillary membrane; and the interstitial tissue contains increasing amounts of extracellular matrix, including elastin and collagen. Secondary alveolar septa form, which partition the terminal saccules into true alveoli, greatly increasing the surface area of the lung available for gas exchange. In the human lung, the alveolar period begins near the time of birth and continues through the first decade of life, during which time, the lung grows primarily by septation, proliferation, and thinning of the alveolar walls,[61] as well as by elongation and luminal enlargement of the conducting airways. Pulmonary arteries enlarge and elongate in close relationship to the increased growth of the lung.[32] Pulmonary vascular resistance decreases, and considerable remodeling of the pulmonary vasculature and capillary bed continue during the postnatal period.[32] Lung growth remains active until early adolescence, when the entire complement of approximately 300 million alveoli has been formed.[61,62]

Signaling pathways that are critical for growth, differentiation, and maturation of the alveolar epithelium and capillary bed during these periods include the FGF, platelet-derived growth factor (PDGF), vascular endothelial growth factor (VGEF), RA, BMP, WNT, β-catenin, and NOTCH signaling pathways. For example, targeted deletion of the FGF receptors, *Fgfr3* and *Fgfr4*, blocks alveologenesis in mice; likewise, targeted deletion of *Pdgfa* interferes with myofibroblast proliferation and migration, resulting in failure of alveologenesis and postnatal alveolar simplification in mice.[8,22,23,25,34,38,40] Notch2, expressed by type II AECs in the developing lung, induces PDGFA expression, activating platelet-derived growth factor receptor (PDGFR) signaling in alveolar myofibroblast progenitors, which is required for myofibroblast differentiation and normal alveologenesis.[63] Recently, a WNT responsive epithelial cell has been identified that serves as a progenitor for both type I and type II AECs during perinatal alveologenesis.[64]

Nuclear transcription factors found earlier in lung development, that is, FOXA2, NKX2-1, GATA6 and SOX2, continue to be important for maturation of the lung, influencing sacculation, alveolarization, vascularization, and cytodifferentiation of the peripheral lung. Transcription factors associated with cytodifferentiation during these periods include (1) FOXJ1 (ciliated cells), (2) MASH1 (or HASH1) and HES1 (neuroendocrine cells), (3) FOXA3 and SPDEF (mucus cells), (4) ETV5/ERM (type II AECs), and (5) HOPX (type I AECs).[22,65] Morphogenesis and cytodifferentiation are further influenced by additional transcription factors expressed in the developing respiratory epithelium at this time, including (1) several ETS factors (ETV5/ERM, SPDEF, ELF3/5); (2) SOX genes (SOX-9, SOX11, SOX17); (3) nuclear factor of activated T cells/calcineurin-dependent signaling (NFATC); (4) nuclear factor-1 (NF-1); (5) CCAAT/enhancer binding protein alpha (CEBP$\alpha$); (6) Krüppel-like factor 5 (KLF5); (7) transcription factors, GLI2/GLI3, SMAD3, FOXF1, POD1, and HOX (HOXA5, HOXB2-B5); all of which are expressed in the mesenchyme.[8,22,23,25,40]

## Molecular Mechanisms Directing Lung Development

Remarkable advances in our understanding of gene regulatory mechanisms are providing an evermore detailed understanding of the processes by which the genetic code is translated into specific cell types and their organization in organs and tissues. Numerous molecular regulatory mechanisms exist to precisely coordinate cell proliferation, lineage commitment, and subsequent terminal differentiation of over 40 distinct, but closely intertwined, cell types that form the mature mammalian lung. Although the “blueprints” for organogenesis are encoded in the organism's genomic DNA, this information must be transmitted to cells of the developing lung by transcribing regions of DNA into messenger RNA (mRNA) and then by translating the mRNAs into protein. These cellular proteins, in turn, influence morphologic, metabolic, and proliferative behaviors of cells throughout development. Points of regulation include control over transcriptional RNA expression, mRNA stability, protein translation, and degradation, as well as further refinement in the abundance of mRNAs and proteins synthesized by each specific cell, which ultimately determine its structure and function. At each step in this cascade of information, numerous regulatory mechanisms exist, and many of which are highly interactive with complex feedback and feed-forward loops, as well as built-in redundancies, to assure precise specification of normal developmental patterns (Fig. 2.4).

**FIG. 2.4** Control of gene expression. Diverse cellular mechanisms regulate varying levels of gene transcription that, in turn, control messenger RNA and protein synthesis governing cell differentiation and function during lung development. Inherited patterns of

each individual's genetic code (A) are modified by epigenetic mechanisms that modify chromatin structure through methylation of DNA and/or modification of histone proteins (B). Binding of nuclear transcription factors to specific structural motifs (cis-acting elements) in DNA sequences is modified by associated cofactors and other transcription factors (C). Protein expression is often controlled by transcriptional networks, in which several genes are activated in series to induce or inhibit expression of downstream targets and/or other proteins (D).

## Transcriptional Mechanisms Regulating Gene Expression

### Transcription Factors and Gene Regulatory Networks

Transcription factors, which are nuclear proteins that bind to specific DNA nucleotide sequences (motifs) in regulatory regions throughout the genome, represent one major mode of transcriptional regulation. The binding of transcriptional factors to the cis-acting elements influences the activity of RNA polymerase II, which binds, in turn, to sequences near the transcription start site of target genes, initiating mRNA synthesis. Transcription factors may recruit additional proteins to the site of binding, modifying various chemical signatures on the DNA or chromatin (e.g., methylation, acetylation) that can continue to influence gene transcription long after the transcription factor itself leaves the region. Numerous families of transcription factors have been identified, and their activities are regulated by a variety of mechanisms, including posttranslational modification and interactions with other proteins or DNA, as well as by their ability to translocate or remain in the nucleus. Due to the large number of individual transcription factors and transcription-binding sites across the genome, these proteins interact combinatorally to form complex gene regulatory networks that direct patterns of gene transcription throughout development.

Although our knowledge of the various factors regulating gene transcription during lung development is still in its infancy, a number of transcription factors and signaling networks that play critical roles in lung morphogenesis have been identified.[8,23,66] A general schematic of important transcriptional regulators of lung epithelial morphogenesis is seen in Figs. 2.5 and 2.6. Lung morphogenesis depends on formation of definitive endoderm, which, in turn, signals from the splanchnic mesenchyme to initiate organogenesis along the foregut, forming thyroid, liver, pancreas, lung, and portions of the gastrointestinal tract.[15,67] FOXA2, a member of the winged helix family of transcription factors, is a "pioneering" transcription factor that is known to play a critical role in committing progenitor cells of the endoderm to form the primitive foregut.[16] Global loss of *Foxa2* in mice results in catastrophic failure of development at the time of gastrulation. Loss of *Foxa2* at later developmental timepoints, alone or in combination with the related transcription factor *Foxa1,* has revealed its essential role in specification of the pancreas and liver and formation of the lung epithelium,[68–70] and it influences the expression of specific genes in the respiratory epithelium later in development. Conditional deletion of *Foxa2* in the lung epithelium of mice highlights its ongoing role in both the proximal and distal lung epithelium. Conditional loss of *Foxa2* prior to birth resulted in impaired maturation of type II cells, altered regulation of surfactant protein and phospholipid production, and death from RDS after birth.[71] Loss of *Foxa2* after birth caused goblet cell metaplasia, airspace enlargement, and inflammation during the postnatal period.[70] Thus, FOXA2 plays a critical role in specification of foregut endoderm in the early embryo, and it is used again in the perinatal and postnatal period to direct surfactant production, alveolarization, postnatal lung function, and homeostasis (see Fig. 2.5).

**FIG. 2.6** Morphogenesis of the conducting and peripheral airway epithelium. The lung bud, visualized by expression of NKX2-1 *(green),* forms from ventral foregut endoderm on embryonic day 9 in the mouse. Endoderm is dependent upon the transcription factors FOXA2 and SOX17. Initiation of lung buds from the foregut endoderm is dependent upon Wnt2/Wnt2b signaling. At E12, bronchial tubes undergo branching morphogenesis marked by NKX2-1 *(green),* while endomucin staining *(red)* identifies endothelial cells. Cells destined to line the conducting airways express SOX2. In contrast, epithelial cells located at the tips of the branches expressing SOX9 and elevated levels of NKX2-1 are progenitors and cells that form the alveoli in the perinatal period. In the human lung, trachea, bronchi, and bronchioles (shown at 20 months of age) are lined primarily by ciliated, basal (stained by TP63), goblet (MUC5B), and other secretory cells, including neuroendocrine cells. In the normal postnatal human lung (shown at 3 years of age), alveoli are lined by squamous, Alveolar Type I that express AGER *(green).* In contrast, cuboidal Alveolar Type II cells express NKX2-1 *(white).* Endothelial cells in alveolar capillaries express PECAM *(red).* The interface between endothelial and alveolar type I cells creates

the efficient gas exchange region that facilitates transport of oxygen and carbon dioxide.

The transcription factor NXK2-1 is the earliest known marker of lung formation. This 38-kd nuclear protein contains a homeodomain DNA-binding motif, and it is critical for formation of the lung and for regulation of a number of highly specific gene products produced selectively in the respiratory epithelium. NKX2-1 is also expressed in the thyroid and in specific regions of the developing central nervous system.[30] Ablation of *Nkx2-1* in mice impairs lung morphogenesis, resulting in hypoplastic lungs lined by a poorly differentiated respiratory epithelium and lacking gas exchange areas.[72] Substitution of a mutant *Nkx2-1* gene that lacks phosphorylation sites substantially rescues lung function in the *Nkx2-1* knockout mouse.[73] *Nkx2-1* directly regulates the transcription of numerous downstream targets, including genes involved in surfactant homeostasis, fluid and electrolyte transport, host defense, and vasculogenesis. Just as important, NKX2-1 functions in concert with other transcription factors, including GATA6, the NF-1 family of transcription factors, STAT3, NFAT, FOXA1/FOXA2, and RARs to form a tightly integrated gene regulatory network to direct lung epithelial development and differentiation. For example, NKX2-1 gene transcription itself is modulated by the activity of FOXA2, which binds to the promoter enhancer region of the NKX2-1 gene, thus creating a transcriptional network.[74] The stoichiometry, timing, and distinct combinations of transcription factors, as well as posttranscriptional modification of these transcription factors, are all critical factors in determining the precise transcriptional output at each stage of development (see Fig. 2.5), and our comprehensive understanding of how these signals are integrated on the systems-level is just beginning to emerge.

## Cis-Regulatory Networks Controlling Gene Expression

Since the launch of the ENCODE (Encyclopedia of DNA elements) project, it has become increasingly clear that a significant fraction of the genome outside of protein-coding genes plays a key role in regulating gene expression.[75] Cis-regulatory elements are a key class of regulatory noncoding DNA sequences, which act to regulate the transcription of a neighboring gene (although the distance of the regulated gene may be many megabases away). Promoters and enhancers are examples of cis-regulatory elements and characteristically contain many transcription factor binding motifs, integrating signals derived from the intricate gene regulatory networks described above. Promoter elements are essential for proper assembly of the key machinery necessary to initiate and establish transcription. Enhancers are "canonically defined as short (~100–1000 bp) noncoding DNA sequences that act to drive transcription independent of their relative distance, location, or orientation to their cognate promoter."[76] Consisting of clusters of transcription factor motifs, combinations of transcription factors interact with enhancer elements, recruit additional cofactor protein complexes, and act combinatorally to interact with the promoter of their regulated gene to modulate gene expression. Genome-wide association studies (GWAS) of many common disorders, including lung diseases such as interstitial pulmonary fibrosis, chronic obstructive pulmonary disease, and asthma, demonstrate that many of the genetic variants identified to date, which have been implicated in susceptibility to these diseases, fall within these noncoding regions of the genome.[77–80] Thus, even though our understanding of the location and function of all cis-regulatory elements (referred to as the "cistrome") critical for proper pulmonary development and function remains limited, a deeper understanding of this area of gene regulation will be essential to make progress in understanding the pathogenesis of a wide variety of common pulmonary disorders.

## Epigenetic Mechanisms: DNA Methylation and Chromatin State

Genomic DNA does not exist in isolation within the cell, but genomic DNA instead is wrapped around proteins called histones in a very orderly fashion that consists of multiple levels of coiling and packing. Both the efficiency or "tightness" with which chromatin is compacted, as well as numerous associated chemical modifications to either the histone proteins or the DNA itself, are emerging as critical mechanisms by which gene expression is regulated during lung development. Methylation of cytosine at position 5 of the pyrimidine ring (largely on cytosines found in the CpG context) is the best studied of these “epigenetic” modifications, with roles in a large variety of biological processes, including X-chromosome inactivation, genomic imprinting, repression of transposable elements, aging, and cancer.[81] In the context of regulating gene expression, methylation of a promoter region generally acts to repress expression of that gene. The promoters of active genes are typically unmethylated regions, or UMRs, whereas distal regulatory elements such as enhancers often have low levels of methylation, or LMRs.[82] These methylation states have been observed to change dynamically during embryonic stem cell models of development and in organ systems such as the brain.[82–84] Moreover, widespread differences in methylation are observed in a variety of lung diseases such as interstitial pulmonary fibrosis.[85] The precise mechanisms, however, by which DNA methylation directs normal development and subsequent homeostasis of the adult lung remain poorly understood. Over 40 posttranslational modifications to the peptide tails of histones have been described, and they are associated with at least a dozen different chromatin “states.”[86] For example, tri-methylation of lysine 4 on histone H3 (notated as H3K4me[3]) is found on active promoter regions, whereas colocalization of H3K4me[1] and H3K27ac mark active enhancers. Other marks, such as H3K27me[3], are found on regions of silenced heterochromatin. Large-scale efforts such as the ENCODE Project and International Human Epigenome Consortium (IHEC) have generated thousands of datasets to create maps of the cis-regulatory landscape in dozens of tissue- and cell-types.[75,87] It is thought that these various chemical marks act to integrate and retain the directions provided by the binding of transcription factors to chromatin throughout development, helping to “lock-in” specific cell fate decisions and provide cellular memory for these transient, but powerful, developmental cues long after they have passed. Dysregulation of chromatin state has recently been recognized to contribute to a wide variety of human disorders from congenital heart disease to lung adenocarcinoma.[88–91] However, whether these posttranslational modifications of histones are merely associated with various regulatory states or play direct and causal roles in regulation of gene expression is just beginning to be explored, particularly in the context of lung development.[92–97]

### Epigenetic Mechanisms: Chromatin Topology/3D Structure

It has long been recognized that many cis-regulatory elements such as enhancers act at great distances, often thousands or even millions of bases-pairs, to regulate the expression of their target genes. Three-dimensional folding of chromatin is essential to mediate these interactions, bringing distant enhancer elements with bound transcription factors and coactivator protein complexes into physical proximity to their target gene promoters.[98,99] Chromatin conformation capture (3C)-based technologies have revealed that the genome is organized into discrete physical domains, called topological-associated domains, or TADs, often forming loops of coregulated genes.[100–103] Other regions of chromatin have been observed to associate with the nuclear membrane (laminin-associated domains or LADs), which typically consist of genes that are silenced or only expressed at low levels, that are thought to help further partition chromatin within the nucleus.[104] Examples of local or global dysregulation of chromatin topology have been reported in human diseases, ranging from blood diseases to Down syndrome, and forced chromatin looping has even been used as a treatment strategy for hemoglobinopathies.[105–107] Future research in this area is likely to have significant implications for our understanding of lung development and pulmonary diseases.

## Nontranscriptional Mechanisms Regulating Morphogenesis

### Noncoding RNA

With the advent of widespread availability of next-generation sequencing-based analysis of RNA, it has become clear that many regions of the genome (as much as 60%–80%) are transcribed into RNA, even if many of these RNAs do not progress to make a protein.[108,109] The transcripts are called “non-coding RNAs” (ncRNA) and are typically divided into two broad categories based on their size: transcripts greater than 200 bp are referred to as “long non-coding RNAs” (lncRNAs), and their smaller counterparts (<200 bp) are referred to as small ncRNAs. A wide variety of small ncRNAs have been described, including microRNAs (miRNAs), small nuclear RNAs (snRNAs), and Piwi-interacting RNAs (piRNAs). A number of miRNAs have been specifically implicated in lung development, including miR-17-92, miR20a, miR-302-367, miR106a-106b, and miR-34/449.[110–115] For example, loss of the miR-17-92 cluster leads to pulmonary hypoplasia due to decreased cellular proliferation, while overexpression enhances proliferation and differentiation of the lung epithelium. More broadly, loss of the Dicer complex, a key component of the machinery necessary to process longer, immature RNA transcripts (pri- or pre-miRNAs) into their mature miRNA form, results in severe defects in branching morphogenesis, and germline mutations in the DICER gene have been identified in familial cases of the rare pediatric lung malignancy pleuropulmonary blastoma.[116,117] Long noncoding RNAs also exhibit dynamic expression patterns throughout development, and new studies have started to unravel important contributions to lung organogenesis.[118–120] An important subset of lncRNAs appears to be genomically positioned near critical transcription factors, including *Nkx2-1, Foxa2,* and *Foxf1.*[119] Loss of the lncRNA, Nanci, adjacent to the transcription factor, *Nkx2-1,* results in a reduction in NKX2-1 expression and recapitulates aspects of the *Nkx2-1* haploinsufficiency phenotype, while loss of the lncRNA, Fendrr, adjacent to *Foxf1* results in a phenotype similar to the human lung developmental disorder alveolar capillary dysplasia.[119,120] Other lncRNAs, such as MALAT1, have been implicated in the pathogenesis of multiple types of malignancy, including lung cancer, but global loss of MALAT1 demonstrated that this lncRNA is not necessary for normal pulmonary development.[121–124] Although individual elements may be dispensable for normal development, it is likely that lncRNAs, similar to miRNAs and many of the other gene regulatory mechanisms discussed earlier, act in highly redundant, coordinated systems to fine-tune gene expression throughout life and will play key roles in response to physiologic stress and disease.

### Receptor-Mediated Signal Transduction

Receptor-mediated signaling is well recognized as a fundamental mechanism for transducing extracellular information. Such signals are initiated by the occupancy of membrane-associated receptors capable of transducing additional signals (known as secondary messengers), such as cyclic adenosine monophosphate, calcium, and inositide phosphates, which influence the activity and function of intracellular proteins (e.g., kinases, phosphatases, and proteases). These proteins, in turn, may alter the abundance of transcription factors, the activity of ion channels, or changes in membrane permeability, which subsequently modify cellular behaviors. Receptor-mediated signal transduction, induced by ligand-receptor binding, mediates endocrine, paracrine, and autocrine interactions on which cell differentiation and organogenesis depend. For example, signaling peptides and their receptors, such as FGF, SHH, WNT, BMP, VEGF, PDGF, and NOTCH have been implicated in organogenesis of many organs, including the lung.[8,22,23,25,34,40,63,66]

### Gradients of Signaling Molecules and Localization of Receptor Molecules

Chemical gradients within tissues, and their interactions with membrane receptors located at distinct sites within the organ, can provide critical information during organogenesis. Polarized cells have basal, lateral, and apical surfaces with distinct subsets of signaling molecules (receptors) that allow the cell to respond in unique ways to focal concentrations of regulatory molecules. Secreted ligands (e.g., FGFs, TGFβ/BMPs, WNTs, SHH, and HHIP1) are further influenced by binding of the ligand to basement membranes or to proteoglycans in the extracellular matrix. Spatial information is established by gradients of these signaling molecules and by the presence and abundance of receptors at specific cellular sites. Such systems provide positional information to the cell, which influences its behavior (e.g., shape, movement, proliferation, differentiation, and polarized transport).

## Epithelial-Mesenchymal Interactions and Lung Morphogenesis

Branching morphogenesis, growth, and differentiation of the respiratory tract depends on precise reciprocal signaling between endodermally derived cells of the lung buds and the surrounding pulmonary mesenchyme. This interdependency depends on autocrine and paracrine interactions that are mediated by a diversity of signaling systems governing cellular behavior.[38,125] Similarly, autocrine and paracrine interactions are known to be involved in cellular responses of the postnatal lung, generating signals that regulate cell proliferation and differentiation necessary for its repair and remodeling following injury. The splanchnic mesenchyme produces a number of signaling peptides critical for migration and proliferation of cells in the lung buds, including FGF10, FGF7, FGF9, BMP5, and WNT 2/2b, which activate receptors found on epithelial cells. In a complementary manner, epithelial cells produce WNT7b, WNT5a, SHH, BMP4, FGF9, VEGF, and PDGF that activate receptors and signaling pathways on target cells in the mesenchyme (see Fig. 2.3).[8,23,25,34]

## Branching Morphogenesis, Vascularization, and Alveologenesis

Three distinct processes, branching, vascularization, and alveologenesis are critical to morphogenesis of the mammalian lung. The major branches of the conducting airways of the human lung are completed by 16 WPC by a process of dichotomous branching, initiated by the bifurcation of the main-stem bronchi early in the embryonic period of lung development. Epithelial-lined tubules of ever-decreasing diameter are formed from the proximal to distal region of the developing lung. The terminal bronchioles divide into two or more respiratory bronchioles, which subdivide further into clusters of acinar tubules and buds at the periphery of the lung. Lung alveologenesis begins in the late canalicular period (16 WPC and thereafter) with expansion of the distal acinar tubules into terminal saccules. Further subdivision of these saccules results in the formation of the adult alveolar ducts and alveoli. During sacculation, a unique pattern of vascular supply forms the capillary network surrounding each terminal saccule, providing an ever-expanding gas exchange area that is completed in adolescence. Both vasculogenesis and angiogenesis contribute to formation of the pulmonary vascular system.[32,34]

The gas-exchange regions of the lung are supplied by the pulmonary arterial system, which originates from the sixth pair of aortic arches. The pulmonary arteries extend into the surrounding mesoderm, where they accompany the developing airways, segmenting with each bronchial subdivision. Ultimately, these arteries anastomose with the pulmonary vascular plexus that is developing in the pulmonary mesenchyme around the peripheral acinar tubules. In contrast, the bronchial vasculature arises from the descending aorta, providing nutrient supply to the conducting airways. The pulmonary veins arise from the left atrium and divide several times before connecting to the pulmonary vascular plexus in the acinar parenchyma, completing the pulmonary circulation.[126] In the adult, these veins are located primarily in the interlobular connective tissue septa that surround each pulmonary lobule.[32,34] Lymphatic vessels form around the bronchi and pulmonary vessels, extending into the interlobular septa and the pleura.[127] Parasympathetic and sympathetic nerve fibers form along the conducting airways and major vascular structures, extending as far as the alveolar ducts.[128] Signaling via SHH, VEGFA, FOXF1, NOTCH, Ephrins, and PDGF plays a significant role in pulmonary vascular development.[8,23,25,34] For example, VEGFA and its receptors (VEGFR1, VEGFR2) are critical factors for vasculogenesis in many tissues. Targeted inactivation of *Vegf* and *Vefgfr1* in mice results in impaired angiogenesis,[129] while overexpression of the VEGFA 164 isoform disrupts pulmonary vascular endothelium in newborn conditional transgenic mice, causing pulmonary hemorrhage.[130] PROX1, a homeodomain transcription factor, is induced in a subset of venous endothelial cells during development and upregulates other lymphatic-specific genes, such as VEGFR3 and LYVE1, which are critical for development of the lymphatic network in the lung.[34] Growth factors important for lymphatic development include VEGFC and its receptor, VEGFR3, as well as the angiopoietins, ANG1 and ANG2, and their receptors, TIE1 and TIE2.[34] Insufficiency or targeted deletion of these factors in mice impairs lymphatic vessel formation.[34,131]

## Control of Lung Proliferation During Branching Morphogenesis

Both *in vitro* and *in vivo* experiments strongly support the concept that the mesenchyme produces signaling peptides and growth factors critical to the formation of respiratory tubules. Dissection of the splanchnic mesenchyme from the lung buds arrests cell proliferation, branching, and differentiation of the pulmonary tubules *in vitro.*[38] Lung growth is influenced by mechanical factors, including the size of the thoracic cavity and by stretch. For example, complete occlusion of the fetal trachea *in utero* enhances lung growth, while drainage of lung liquid or amniotic fluid causes pulmonary hypoplasia.[132,133] Regional control of proliferation is required for the process of branching morphogenesis: division is enhanced at the lateral edges of the growing bud and inhibited at branch points.[134] Precise positional control of cell division is determined by polypeptides derived from the mesenchyme (e.g., growth factors or extracellular matrix molecules) that selectively decrease proliferation at clefts and increase cell proliferation at the edges of the bud. Proliferation in the respiratory tubule is dependent on a number of growth factors, including the FGF family of polypeptides. *In vitro,* FGF1, and FGF7 partially replace the requirement of pulmonary mesenchyme for continued epithelial cell proliferation and budding.[135,136] FGF10 produced by the mesenchyme during lung development binds to and activates a splice variant of FGFR2 (FGFR2IIIb) that is present on respiratory epithelial cells, completing a paracrine loop.[137] Blockade of FGFR2 signaling in the epithelium of the developing lung bud *in vivo,* using a dominant-negative FGF receptor mutant, completely blocked dichotomous branching of all conducting airway segments except the primary bronchi in mice.[138] FGF10 produced at localized regions of mesenchyme near the tips of the lung buds creates a chemoattractant gradient that activates the FGFR2IIIb receptor in epithelial cells of the lung buds, inducing cell migration, differentiation, and proliferation required for branching morphogenesis.[139] Deletion of *Fgf10* or *Fgfr2IIIb* in mice blocked lung bud formation, resulting in pulmonary agenesis.[140,141] Increased expression of FGF10 or FGF7 in the fetal mouse lung caused severe pulmonary lesions with all of the histologic features of cystic adenomatoid malformations.[142,143] Actions of FGF10 in the mesenchyme are countered by expression of BMP-4 by epithelial cells in the lung buds that together control branching morphogenesis.[144,145] Bidirectional paracrine signaling between mesenchymal and epithelial cells is mediated by a diversity of signaling networks. For example, FGF9, produced primarily by lung mesothelial and epithelial cells, is required for normal growth of the pulmonary mesenchyme.[146] Examples of signaling polypeptides known to influence branching morphogenesis and differentiation of the respiratory tract are listed in Box 2.1.

**Box 2.1**

### Examples of Secreted Growth Factors Influencing Lung Morphogenesis and Cell Differentiation

Sonic hedgehog (SHH)
Retinoic Acid (RA)
WNT family members (WNT2/2b, 4, 7b, 5a, and R-spondin)
Fibroblast growth factors (FGF1, FGF7, FGF9, FGF10)
Bone morphogenic proteins (BMP4)
Transforming growth factor-β (TGFβ)
Vascular endothelial growth factor (VEGFA, VEGFC)
Platelet-derived growth factor (PDGFA, PDGFB)
Epidermal/transforming growth factors (EGF/TGFa)
Hepatocyte growth factor (HGF)
Insulin-like growth factors (IGFI, IGF2)
Granulocyte-macrophage colony-stimulating factor (GM-CSF)

## Role of Extracellular Matrix, Cell Adhesion, and Cell Shape

The pulmonary mesenchyme is relatively loosely packed, and there is little evidence that cell type is specified during the early embryonic period of lung development. However, with advancing gestation, increasing abundance of extracellular matrix molecules, including laminin, fibronectin, collagens, elastin and proteoglycans, is readily detected in the mesenchyme adjacent to the developing epithelial structures.[147–153] Variability in the presence and abundance of various matrix molecules within the mesenchyme influences structural development, cytodifferentiation and cell interactions *in vivo. In vitro,* inhibitors of collagen, elastin, and glycosaminoglycan synthesis, as well as antibodies to various extracellular and cell attachment molecules, alter cell proliferation and branching morphogenesis of the embryonic lung. Mesenchymal cells differentiate to form vascular elements (endothelium and smooth muscle) and distinct fibroblastic cells (matrix, myofibroblasts, and lipofibroblasts), which arise from the relatively undifferentiated progenitor cells of the splanchnic mesenchyme. While little is known regarding the factors influencing differentiation of the pulmonary mesenchyme, the development of pulmonary vasculature is dependent on VEGF, while differentiated smooth muscle is dependent upon SHH.[34,144] VEGFA is secreted by respiratory epithelial cells, stimulating pulmonary vasculogenesis via paracrine signaling to receptors that are expressed by progenitor cells in the mesenchyme.[154–157] PDGFA, another growth factor secreted by the respiratory epithelium, influences proliferation and differentiation of myofibroblasts in the developing lung by binding to the PDGF alpha receptor, and deletion of *Pdgfa* causes pulmonary malformation in transgenic mice.[158] The organization of both mesenchyme and epithelium is further modulated by cell adhesion molecules of various classes, including the cadherins, integrins, and polypeptides forming cell-cell junctions, which contribute to cellular organization and polarity of various tissues during pulmonary organogenesis. Furthermore, the surrounding extracellular matrix contains adhesion molecules that interact with attachment sites at cell membranes, influencing cell shape and polarity.[150,151] Cell shape is determined, at least in part, by the organization of these cell attachment molecules to the cytoskeleton. Cell shape, polarity, and mobility are further influenced by cytoskeletal proteins that interact with the extracellular matrix, as well as neighboring cells. The planar cell polarity (PCP) pathway and its downstream effector, Rho kinase, are critical for branching morphogenesis *in vivo* through their effects on cytoskeletal remodeling and organization, which influence apical-basal polarity within epithelia.[159,160] Mutations in the genes, *Celsr1* and *Vangl2* that are key components of the PCP pathway, disrupted the actin-myosin cytoskeleton during mouse lung development, resulting in hypoplastic lungs with fewer branches and terminal buds, thickened mesenchyme, and highly disorganized epithelia with narrow or absent lumina.[161]

Cell shape also influences intracellular routing of cellular proteins and secretory products, determining sites of secretion. *In vitro,* epithelial cells grown on intracellular matrix gels at an air-liquid interface form a highly polarized cuboidal epithelium that maintains cell differentiation and polarity of secretions *in vitro.* Changes in cell shape are associated with the loss of differentiated features, such as surfactant protein and lipid synthesis, demonstrating the profound influence of cell shape on gene expression and cell behavior.[162–164]

## Autocrine-Paracrine Interactions in Lung Injury and Repair

As in lung morphogenesis, autocrine-paracrine signaling plays a critical role in the process of repair following lung injury.[66] The repair processes in the postnatal lung, as in lung morphogenesis, require the precise control of cell proliferation and differentiation and, as such, are likely influenced by many of the signaling molecules and transcriptional mechanisms that mediate lung development. Events involved in lung repair may recapitulate events occurring during development, in which progenitor cells undergo proliferation and terminal differentiation after lung injury. While many of the mechanisms involved in lung repair and development may be shared, it is also clear that fetal and postnatal lung respond in distinct ways to autocrine-paracrine signals. Cells of the postnatal lung have undergone distinct phases of differentiation and may have different proliferative potentials and/or respond in unique ways to the signals evoked by lung injury. For example, after acute or chronic injury, increased production of growth factors or cytokines may influence fibrosis or pulmonary vascular remodeling in neonatal life and be mediated by processes distinct from those occurring during normal lung morphogenesis.[165–170] The role of inflammation and the increasing activity of the immune system that accompanies postnatal development also distinguishes the pathogenesis of disease in fetal and postnatal lungs.

# Development of the Pulmonary Host Defense Systems

## Mucociliary Clearance

After birth, the lung is constantly exposed to particles, pathogens, and toxicants that are removed primarily by mucociliary clearance.[171] The human airways are lined by a pseudostratified epithelium, consisting of basal, ciliated, neuroendocrine and various secretory cells (e.g., goblet, Club, and brush cells), that form a robust barrier, control airway hydration and mucociliary escalation, and protect the airway and lung from infection and injury. The critical importance of mucociliary clearance in human physiology is exemplified by the recurrent life threatening infections associated with cystic fibrosis (CF) and primary ciliary dyskinesia (PCD), wherein abnormalities in mucus hydration and in ciliary proteins, respectively, impair airway clearance causing bronchiectasis.[172–174]

## Innate and Acquired Immunity

Distinct innate and adaptive defense systems mediate various aspects of host responses in the lung (see Chapter 8).[171] During the postnatal period, the numbers and types of immune cells present in the lung expand markedly.[175] Alveolar and tissue macrophages, dendritic cells, innate lymphocytes and classical lymphocytes of various subtypes, polymorphonuclear cells, eosinophils, and mast cells each have distinct roles in host defense. Immune cells mediate acute and chronic inflammatory responses accompanying lung injury or infection. Both the respiratory epithelium and inflammatory cells are capable of releasing and responding to a variety of polypeptides that induce the expression of genes involved in (1) cytoprotection (e.g., antioxidants, heat shock proteins); (2) adhesion, influencing the attraction and binding of inflammatory cells to epithelial and endothelial cells of the lung; (3) cell proliferation, apoptosis and differentiation that follow injury or infection; and (4) innate host defense. Multiple cytokines and chemokines recruit and activate the remarkable diversity of lymphocytes, innate lymphoid, monocytic, and myeloid cells that reside in the lung where they play critical roles in protecting the lung from microbial pathogens, particles, and toxicants.[176,177]

The adaptive immune system includes both antibody and cell-mediated responses to antigenic stimuli. Adaptive immunity depends on the presentation of antigens by macrophages, dendritic cells, or the respiratory epithelium to mononuclear cells, triggering the expansion of immune lymphocytes and initiating antibody production and cytotoxic activity needed to remove infected cells from the lung. The lung contains active lymphocytes (natural killer cells, helper and cytotoxic T cells) that are present within the parenchyma and alveolus. Organized populations of mononuclear cells are also found in the lymphatic system along the conducting airways, termed the *bronchus-associated lymphoid tissue*. Cytokines and chemokines, including (1) interleukin (IL) 1, or IL1, (2) IL8, (3) tumor necrosis factor-$\alpha$, or TNF$\alpha$, (4) regulated on activation, normal T-expressed and secreted protein, or RANTES, (5) granulocyte-macrophage colony-stimulating factor, or GM-CSF, and (6) macrophage inflammatory protein-1$\alpha$, or MIP-1$\alpha$, are produced by cells in the lung. They provide proliferation and/or differentiation signals to inflammatory cells that, in turn, amplify these signals by releasing additional cytokines or other inflammatory mediators within the lung.[176] Receptors for some of these signaling molecules have been identified in pulmonary epithelial cells. For example, GM-CSF plays a critical role in surfactant homeostasis. Genetic ablation of GM-CSF or GM-CSF-IL3/5β chain receptor in mice causes alveolar proteinosis associated with macrophage dysfunction and surfactant accumulation.[178–182] Pulmonary alveolar proteinosis in adult human patients is associated with high-affinity autoantibodies against GM-CSF that block receptor activation required for surfactant catabolism by alveolar macrophages.[183,184] Inherited defects in the GM-CSF receptor, including both the GM-CSF receptor alpha and beta chains, have been associated with alveolar proteinosis in children.[183,184] GM-CSF stimulates both differentiation and proliferation of type II AECs, as well as activating alveolar macrophages to increase surfactant catabolism. Thus, GM-CSF acts in an autocrine and paracrine fashion as a growth factor for both the respiratory epithelium and for alveolar macrophages. A number of additional growth factors, including FGFs, EGF, TGF$\alpha$, PDGF, IGFs, TGFβ and others, are released by lung cells following injury. These polypeptide growth factors likely play a critical role in stimulating proliferation of the respiratory epithelial cells required to repair the injured respiratory epithelium.[170,176] For example, intratracheal administration of FGF7 causes marked proliferation of the adult respiratory epithelium and protects the lung from various injuries.[185]

## Innate Defenses

The respiratory epithelium and other lung cells secrete a variety of polypeptides that serve defense functions, including bactericidal polypeptides, lysozyme, defensins, collectins (surfactant proteins, SFTPA and SFTPD), and other polypeptides that enhance macrophage activity involved in the clearance of bacteria and other pathogens. SFTPA and SFTPD, both members of the collectin family of mammalian lectins, are secreted by the respiratory epithelium and bind to pathogenic organisms, enhancing their phagocytosis by alveolar macrophages.[186–189] Polypeptide factors with bactericidal activity, such as lactoferrin, lysozyme, and defensins are produced by pulmonary cells in response to inflammation.[190] Thus, the immune system and accompanying production of chemokines and cytokines serve in an autocrine-paracrine fashion to modulate expression of genes mediating innate and immune-dependent defenses, as well as cell growth, critical for the repair of the parenchyma after injury. Uncontrolled proliferation of stromal cells leads to pulmonary fibrosis just as uncontrolled growth of the respiratory epithelium produces pulmonary adenocarcinoma.

Chronic inflammation, whether through inhaled particles, infection, or immune responses, may therefore establish ongoing inflammatory and proliferative cascades that lead to fibrosis and abnormal alveolar remodeling associated with chronic lung disease.[191]

## Gene Mutations in Lung Development and Function

Knowledge of the role of specific genes in lung development and function is expanding rapidly, extending our understanding of the role of genetic mutations that cause lung malformation and disease. Mutations in the DNA code may alter the abundance and function of encoded polypeptides, causing changes in cell behavior that lead to lung malformation and dysfunction.

Mutations in NKX2-1 cause neurological symptoms, hypothyroidism, and neonatal RDS followed by development of a chronic interstitial lung disease, the latter caused by disrupted surfactant homeostasis and pulmonary hypoplasia.[192–201] Mutations in SOX9 result in respiratory insufficiency due to severe tracheobronchomalacia in campomelic dwarfism,[202–206] while mutations in SOX2 have been associated with tracheoesophageal fistula, anophthalmia, microphthalmia, and central nervous system defects.[207] Similarly, defects in SHH (for example, GLI3 gene mutations) and FGF (e.g., FGFR2 mutations) signaling have been associated with lung and tracheobronchial malformations in human infants.[208,209] Mutations in the transcription factor, FOXF1, have been causally linked to the lethal congenital malformation, alveolar capillary dysplasia with misalignment of the pulmonary veins.[210,211] Thus, it is increasingly apparent that mutations in genes, or their regulatory elements, that influence transcriptional and signaling networks that control lung morphogenesis cause pulmonary malformations in infants. It is highly likely that allelic diversity in genes influencing lung morphogenesis will impact postnatal lung homeostasis and disease pathogenesis. Findings that SOX2 and NKX2-1 are frequently amplified in adults with squamous and nonsmall cell adenocarcinoma, respectively, links processes controlling morphogenesis with those regulating epithelial cell proliferation and tumorigenesis in the respiratory tract.[212–214]

Postnatally, mutations in various genes critical to lung function, host defense, and inflammation are associated with severe pulmonary disease. Some hereditary disorders affecting lung function include (1) CF, caused by mutations in the cystic fibrosis transmembrane conductance regulator *(CFTR)* protein[215]; (2) PCD caused by mutations in multiple genes associated with ciliary structure and/or function[173,174]; (3) emphysema, caused by mutations in $\alpha_1$-antitrypsin[216]; (4) lymphangioleiomyomatosis, caused by mutations in tuberous sclerosis complex 1 and 2 *(TSC1/2)*[217]; (5) alveolar proteinosis, caused by mutations in the GM-CSF receptor *(GMCSFR)*[183]; (6) acute respiratory failure in neonates caused by mutations in *SFTPB* and ABCA3[218]; (7) chronic interstitial lung disease in infants and children caused by mutations in *SFTPC, ABCA3,* and *NKX2-1* genes[53]; (8) chronic interstitial lung disease with progression to pulmonary fibrosis in adults caused by mutations in the *SFTPA, SFTPC, ABCA3,* and in genes controlling the length of telomeres *(TERT, TERC).*[53,219] Mutations in signaling systems controlling countless primary immune cell functions lead to pulmonary infections.[220] The severity of disease associated with these monogenetic disordersis often strongly influenced by other inherited genes or environmental factors (e.g., smoking) that ameliorate or exacerbate underlying lung disease. The identification of "modifier genes" and the role of gene dosage in disease susceptibility will be critical in understanding the pathogenesis and clinical course of pulmonary disease in the future.

## Summary

The molecular and cellular mechanisms controlling lung morphogenesis and function provide a fundamental basis for understanding the pathogenesis and therapy of pulmonary diseases in children and adults. Future advances in pulmonary medicine will depend on the identification of genes, and their encoded polypeptides, that play critical roles in lung formation and function. Knowledge regarding the complex signaling pathways that govern lung cell behaviors during development and after injury will provide the basis for new diagnostic and therapeutic approaches that will influence clinical outcomes. Diagnosis of pulmonary disease will be facilitated by the identification of new gene mutations that cause abnormalities in lung development and function. Since many of the events underlying lung morphogenesis are likely to be involved in the pathogenesis of lung disease postnatally, elucidation of molecular pathways governing lung development will provide the knowledge needed to understand the cellular and molecular basis of lung diseases. Advances in recombinant DNA technology and the ability to synthesize bioactive polypeptides and to add or delete genes via DNA transfer are also likely to influence the therapy of pulmonary disease in the future.

# Basic Genetics and Epigenetics of Childhood Lung Disease

*Jennifer Wambach MD, MS, Bimal Pankaj Chaudhari MD, MPH, Aaron Hamvas MD*

Childhood disease results from the interplay of genetic, environmental, and developmental factors (Fig. 3.1). The rapid development of DNA technologies has permitted the identification of the molecular basis of more than 5500 disorders caused by functional variation in more than 3500 genes (Online Mendelian Inheritance in Man, http://omim.org/statistics/geneMap, accessed June 28, 2016), including more than 100 monogenic lung diseases that contribute to a significant burden of pediatric pulmonary conditions. Cystic fibrosis resulting from disruption of *CFTR* is the most common of these monogenic pulmonary disorders, affecting 1 of 3000 births in Northern European populations.[1] In contrast, asthma is the most common respiratory disease of childhood, affecting more than 300 million individuals worldwide. Although asthma is a heritable disease, multiple candidate genes have been identified, each of which individually explains only a small proportion of this heritability.[2–5]

Genetic

**FIG. 3.1** Developmental, environmental, and genetic inputs that interact to result in a pulmonary phenotype and specific examples of each. For example, premature birth increases the risk for neonatal respiratory distress syndrome (RDS) or bronchopulmonary dysplasia, but specific intrauterine exposures, such as infection, or genetic susceptibility may influence the severity of the phenotype. Conversely, antenatal corticosteroids decrease the risk and severity of neonatal RDS for infants born prematurely. The developmental and environmental inputs are partially mediated by epigenetic mechanisms. *PCD,* Primary ciliary dyskinesia.

The availability of high-throughput sequencing has permitted extensive investigation into the “gene” arm of the gene × environment × development interaction, especially for complex traits like asthma, bronchopulmonary dysplasia (BPD), or neonatal respiratory distress syndrome (RDS) where evidence of heritability is present, but for which identified genetic variation explains only a small proportion of disease risk. For example, disparate outcomes of monozygotic twins suggest that genetic factors account for 50%–80% of the risk for BPD[6,7] and approximately 50%–60% of the risk for neonatal RDS,[8,9] but variation in identified genes accounts for only approximately 10% of this risk in RDS.[10] Aside from the fact that only a limited number of genes or individuals have been studied, other sources of this “missing heritability” include environmental and developmental interactions, some of which are epigenetic. BPD, primarily a condition of premature infants, is a classic example of how developmental factors are integral to the mechanisms of disease. An exquisitely coordinated repertoire of genes interacts to form a lung that is structurally and functionally mature to exchange gas once birth occurs, but premature birth at a time when the lung is structurally and functionally immature has the potential to disrupt this cascade of normal development.[11–13] Variation in developmentally expressed genes that are critical for lung maturation can contribute to abnormal lung development after premature birth and lung injury but would otherwise be silent in babies born at term.

Virtually all known mechanisms of genetic or genomic variation can cause pediatric lung diseases. A basic understanding of the types of variation is crucial to appreciating the advantages and limitations to various methods of genetic testing in current clinical use, as well as interpreting a rapidly expanding body of literature on the genetic basis of both monogenic and complex lung disease. Here we review some genetic terminology (Table 3.1) and current strategies for genetic testing, but the reader may also wish to consult several excellent textbooks or review articles for more detail.[14,17] The reader is also referred to the Human Genome Organization (HUGO) guidelines for gene nomenclature (www.genenames.org).

## Table 3.1

## Common Genetic Terminology

| BASIC TERMINOLOGY | |
|---|---|
| DNA | Double helix–shaped molecule composed of nucleotides that contains code for protein synthesis |
| Nucleotide | Basic molecules of DNA and RNA composed of sugars, phosphates, and nitrogenous bases: adenine, cytosine, guanine, thymine [A, C, G, T] for DNA; adenine, cytosine, guanine, uracil [A, C, G, U] for RNA |
| Gene | Sequence of DNA nucleotides that specifies amino acid order for a specific protein |
| RNA | Typically single-stranded molecule composed of nucleotides that is transcribed from DNA and is essential for protein synthesis (messenger, transfer, and ribosomal RNA [mRNA, tRNA, rRNA]) |
| Exon | The “coding” portion of a gene—the sequence that is transcribed into a messenger RNA for subsequent translation into a protein |

| | |
|---|---|
| Intron | The "noncoding" portion of a gene—important in regulation of gene expression |
| Complementary DNA (cDNA) | DNA sequence that is derived from reverse transcription of messenger RNA, commonly used to denote the location of a variant within a gene (e.g., c.456 G > T) |
| Transcription | Process of copying DNA into RNA |
| Translation | Process of synthesizing protein from RNA |
| Exome | Portion of the genome formed by the exons or protein coding regions (~1% of human genome) |
| Genome | Full genetic complement of an individual organism (3 billion base pairs in human) |
| Genotype | Specific combination of alleles for a particular gene or locus |
| Phenotype | Observable characteristic of an individual/organism resulting from interaction of genotype with environment |
| Pleiotropy | One gene affects more than one phenotypic trait |
| Polygenic trait | More than one gene contributes to a phenotypic trait |
| Allele | Alternative form of a gene that may occur at a given gene locus |
| Homozygous | Having two identical alleles at a gene locus |
| Heterozygous | Having two different alleles at a gene locus |
| Dominant allele | Gene that is phenotypically expressed whether or not the other allele is identical |
| Recessive allele | Gene that is phenotypically expressed when the other allele is identical, but whose expression is masked in presence of dominant allele |
| Haplotype | Group of variants on a single chromosome that are inherited together |
| LD | Nonrandom assortment of alleles at different genetic loci |
| TagSNP | Single nucleotide polymorphism in a region of the genome with high linkage disequilibrium that is informative of additional variants at other genomic positions |
| Recombination | Rearrangement of genetic material resulting from crossing over of chromosomes during meiosis |
| Germline variant | Variant in DNA sequence transmitted by egg or sperm, presumed to be present in all nucleated cells |
| Somatic variant | Variant in DNA sequence arising in a specific tissue, presumed to be present in all cells derived from original progenitor cell |
| Monozygotic twins | Twins resulting from a single zygote (single egg, single sperm) that separates in early development |
| Dizygotic twins | Twins resulting from two separate zygotes (two eggs, two sperm) |
| **TYPES OF GENETIC VARIATION** | |
| SNV | Variation in DNA sequence occurring at a single nucleotide position; variants with a frequency >1% are commonly called SNPs |
| Synonymous variant | A single nucleotide variant that does not result in a change in the amino acid at that location |
| Nonsynonymous variant | A single nucleotide variant that results in a change in the amino acid at that location; also called a missense variant |
| Nonsense variant | Single nucleotide change that results in a premature stop in transcription which results in an unstable messenger RNA that is unable to be translated or, if translated, a truncated and often nonfunctional protein product |
| CNV | Deletions or amplifications (e.g., duplications, triplications) of chromosomal segments; can arise during meiosis or somatic divisions |
| Insertion/deletion "indels" | Insertions—extra nucleotides are inserted into the DNA sequence<br>Deletions—nucleotides are deleted from the DNA sequence |
| In-frame indel | Insertion or deletion of multiples of three nucleotides that add or delete amino acids without disrupting the remainder of the amino acid sequence |
| Frameshift indel | Insertion or deletion of nucleotides that disrupt the reading frame and the remainder of the amino acid sequence |
| Mutation | Any variation in the nucleotide sequence of a gene; however, it typically |

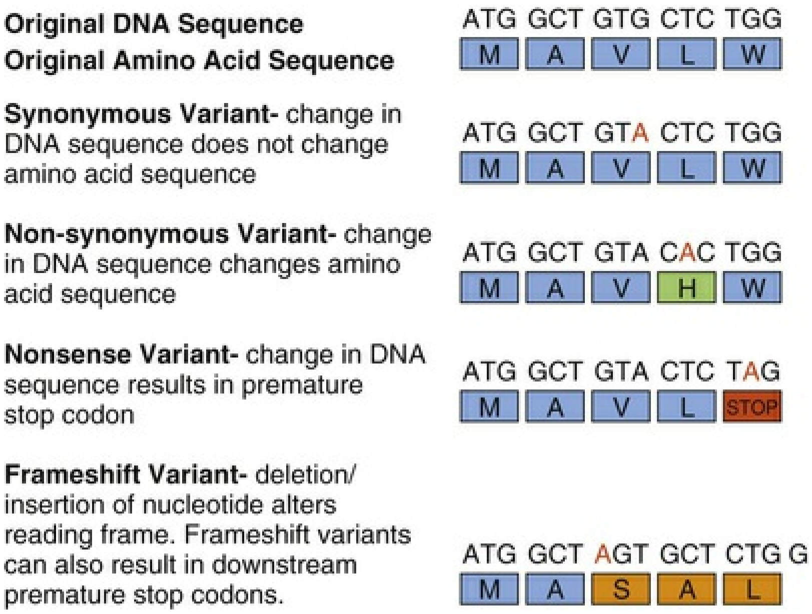
| | |
|---|---|
| | connotes a deleterious effect. All of the aforementioned variants are technically "mutations." The terminology is migrating to the following classification scheme. |
| **VARIANT CLASSIFICATION**[16] | |
| Pathogenic | Very strong or strong evidence that a variant is disease causing |
| Likely pathogenic | Strong to moderate evidence that a variant is disease causing |
| VUS | DNA changes with too little information known to classify functionality |
| Likely benign | Strong to supporting evidence that a variant is not disease causing |
| Benign | Strong evidence that a variant is not disease causing |

*CNV*, Copy number variation; *LD*, linkage disequilibrium; *SNP*, single nucleotide polymorphisms; *SNV*, single nucleotide variant; *VUS*, variant of uncertain significance.

From references 14, 15, and 16.

# Types of Genetic Variation

Genetic variation comes in many forms, and single nucleotide variants (SNVs), small insertions/deletions (indels), exonic deletions, and trinucleotide repeats have all demonstrated roles in the pathogenesis of lung disease (Fig. 3.2). SNVs are single nucleotide changes in the genome and can occur in coding and noncoding regions. SNVs in coding regions can have relatively little effect on protein function (e.g., no change in amino acid sequence [synonymous] or conservative amino acid substitution), can result in a truncated or nonfunctional protein (e.g., nonsense, frameshift SNVs), or can have intermediate effects (nonconservative missense, splice site, and in-frame indels). SNVs that are present in greater than 1% of the population (minor allele frequency $> 0.01$) are referred to as single nucleotide polymorphisms (SNPs), and these "common" variants have enabled research methodologies, including genome-wide association studies (GWAS). SNVs present in less than 1% of the population are termed "rare" variants, and, although most are still of modest effect size, they are more likely to have larger effect sizes than SNPs.[18] The term "mutation," often used interchangeably with SNVs and SNPs, has a more negative connotation and may even imply a "disease-causing change," whereas the term "polymorphism" has a more neutral connotation and indicates a more common variant.[19] Indels may affect one or more nucleotides and can be "in-frame," meaning they occur in multiples of three nucleotides and add or delete amino acids in that region without disrupting the remainder of the amino acid sequence, or they can cause a “frameshift,” meaning they disrupt the reading frame and all subsequent amino acid sequence. In-frame indels generally result in less disruption to the reading frame, but, as evidenced by the delF508 mutation in *CFTR,* even the deletion of three bases and a single amino acid can be deleterious. Indels that result in addition or deletion of bases that shift the reading frame are frequently pathogenic.



**Original DNA Sequence**
**Original Amino Acid Sequence**
ATG GCT GTG CTC TGG

**Nonsense Variant-** change in DNA sequence results in premature stop codon
ATG GCT GTA CTC TAG
M A V L STOP
**Frameshift Variant-** deletion/ insertion of nucleotide alters reading frame. Frameshift variants can also result in downstream premature stop codons.
ATG GCT AGT GCT CTG G
M A S A L

**FIG. 3.2** Types of single nucleotide variation. A representative DNA sequence of nucleotide triplets comprising a codon and the corresponding encoded amino acid *(blue box)* is shown at the top. A single nucleotide substitution *(red)* may have no effect on amino acid sequence (synonymous), may change the amino acid sequence (nonsynonymous), or may encode a signal (TAG) to stop transcription prematurely, which typically results in an unstable mRNA and absence of detectable protein. An insertion (or deletion) of a single nucleotide changes the triplet reading frame and changes the subsequent amino acid sequence.

Although the vast majority of monogenic lung disease is caused by SNVs, there are important examples of less common genetic variation causing lung disease. For example, the absence of dozens or hundreds of base pairs encompassing one or more exons (so-called exonic deletions) can cause serious disease. For the pulmonologist the prime examples are Duchenne and Becker muscular dystrophies. Methods for assaying SNVs including Sanger sequencing will not reliably detect exon skipping (see Table 3.3 later in this chapter), and methods such as multiplex ligation-dependent probe amplification (MLPA) must be used when there is high clinical suspicion for these disorders.[20] Disorders such as myotonic dystrophy result from expansion of three nucleotide repeat (so-called trinucleotide repeat) regions in coding regions that result in unstable and abnormal proteins. Methods for assaying SNVs will not reliably detect trinucleotide repeats, and methods such as polymerase chain reaction (PCR) must be used when there is high clinical suspicion for these disorders.[21]

In addition to single gene variation, copy number variation (deletions, duplications) may occur at the whole chromosome level (e.g., trisomy 13, 18, 21), where pulmonary effects are largely of secondary importance as compared with other organ dysfunction, but also at the microscopic or submicroscopic level, affecting only a portion of a single chromosome or as a translocation involving two or more chromosomes. Autosomal dominant disorders may be caused by deletions, autosomal recessive conditions may be unmasked by deletion of the "normal" allele, and translocations with breakpoints within a given gene may cause similar effects.

## Technologies to Identify Genetic Variation

The Human Genome Project, with initial sequencing completed in 2001, has led to the development of multiple technologies of relevance to pediatric lung disease from both clinical and research perspectives.[22] These technologies are being increasingly integrated into clinical medicine, often blurring the lines between clinical diagnostic evaluation and research. Thus it is important to understand both the technologies in current clinical use, as well as those being used on a research basis, to interpret an emerging body of literature and to anticipate the maturation of such technologies for clinical application (see Table 3.2).

| ClinVar | http://www.ncbi.nlm.nih.gov/clinvar/ |

Historically, chromosomal or cytogenetic variation was assayed using the classical karyotype or fluorescent in situ hybridization (FISH); however, array-based technologies have become more prevalent in both research and clinical care. Chromosomal microarray (CMA) consists of hundreds of thousands to millions of DNA probes (as oligonucleotides with or without SNPs) spotted onto a solid surface. DNA (or RNA) is hybridized to these probes, and hybridization is measured by a fluorescent reporter. CMA can assess for copy number variation (microdeletions, microduplications, and unbalanced translocations) and (when SNPs are used) regions of excessive homozygosity, suggesting increased risk for recessive or imprinting disorders. Although often used as a first-line tool for genetic analysis, CMA will not detect small changes in the sequence of single genes including point mutations, tiny duplications or deletions within a single gene (e.g., between array probes), or balanced chromosomal rearrangements (translocations, inversions). Microarray can also be used to assess RNA expression as a research tool (e.g., comparing RNA transcripts for an SNV predicted to alter exon-intron splicing).

The International HapMap Project demonstrated that SNPs at different positions in the genome are frequently inherited together, a phenomenon known as linkage disequilibrium.[23,24] Although millions of SNPs were present in the human genome, one could infer, through linkage disequilibrium, many more variants by sequencing only a subset of these “tagSNPs.”[25] The use of tagSNPs facilitated the rise of GWAS using arrays that contain up to 2 million previously identified variants.

The Human Genome Project also fostered significant advancement in sequencing technologies. Classically, sequencing of single genes was done by Sanger sequencing.[26,27] Highly reliable and able to generate reads of greater than 500 base pairs, Sanger sequencing is still used to validate limited numbers of selected variants generated by high-throughput sequencing technologies; however, it does not scale well to sequence multiple genes. “Next-generation” sequencing technologies allow rapid sequencing of hundreds of genes or even whole exomes or genomes simultaneously by combining microarray technology and parallel sequencing of short reads (50–400 base pairs) with computational techniques to align the fragments to a reference sequence.[28–30]

Whole exome sequencing (WES) targets the exonic (protein coding) regions of all approximately 20,000 genes in the genome simultaneously and has become a widely used clinical diagnostic tool to identify rare sequence variants in patients with a phenotype suspected to be due to disruption of a single gene.[15] However, exons comprise only approximately 1% of the genome. Whole genome sequencing (WGS) has therefore emerged as a diagnostic tool and offers several advantages over exome sequencing, including detection of structural variation and variation in nonexonic regulatory, intronic, and intergenic regions. In silico programs to interpret structural and noncoding variation are emerging but lag behind those used for coding variation; currently, genome sequencing is not widely available and is significantly more expensive than exome sequencing.[31,32] Clinical exome and genome sequencing is estimated to identify a causative variant in approximately 25% of trios (affected child plus both parents), but this depends largely on patient selection based on phenotype, family history, and suspected inheritance pattern.[33] Clinical exome and genome sequencing can lead to the identification of previously identified variants or suspected pathogenic variant(s) in a gene *known* to be associated with human disease. Alternatively, exome or genome sequencing may identify suspected pathogenic variants in a gene not previously associated with a human phenotype, in which case additional clinical or laboratory investigation may be needed to establish pathogenicity. Positive results from clinical exome or genome sequencing are highly accurate, but false-negative results can occur, depending on the quality of data from a specific genomic region. In addition, the clinician must consider how well the putative variant(s) explains the patient's phenotype in terms of clinical assessment and interpretation of existing medical literature.[15] In some individuals, more than one candidate gene may be identified or, alternatively, no candidate variants may be identified. Reasons for negative findings include lack of coverage of a genomic region, limitations of variant prediction algorithms, polygenic inheritance, epigenetic mechanisms, or lack of an underlying genetic etiology. Reanalysis of sequence data may be of use as variant prediction algorithms mature, additional patients with similar phenotypes are reported, and the functions of additional genes are characterized.

## Interpretation of Genetic Variation

Because each individual has millions of genetic variants, the vast majority of which are functionally insignificant, the principal challenges of sequencing are interpretation, as opposed to sequence generation.[34] For previously described SNVs many databases exist to assist in interpretation or classification, examples of which are listed in Table 3.2. Some programs, such as ANNOVAR, efficiently combine the results of multiple in silico prediction algorithms.[35] However, it should be noted that such databases are not infallible and variant classification is very dynamic (i.e., a variant that might be classified as “benign” or “of unknown significance” might be reclassified with accumulation of additional information). ClinVar provides the most current cataloging of these variants and also allows for conflicting interpretations of the same variant(http://www.ncbi.nlm.nih.gov/clinvar/).[36] Furthermore, because sequencing has the potential of identifying novel variants, both the clinician and the researcher must have a basic understanding of *in silico* prediction methods and their limitations. Wu and Jiang provide an overview of available tools for this purpose and caution that, although specific algorithms may outperform others under specific conditions, best results are typically obtained by using multiple algorithms and integrating knowledge over all available domains.[37] In addition to *in silico* prediction algorithms, functional studies and identification of variants in other diseased (or nondiseased) individuals can also aid in variant interpretation. Given the limitations of *in silico* prediction, there is increasing demand for biologic confirmation of *in silico* predictions. Although a detailed exploration of the various methods of developing model systems is beyond the scope of this chapter, special attention should be paid to the emerging technology of CRISPR/Cas9, which permits targeted genome editing and is being applied to existing model organisms to test functionality suggested by *in silico* prediction tools.[38]

If one takes a genomic approach and obtains WES/WGS, many (most) of the genes sequenced and variants that are identified will not have anything to do with the clinical phenotype. Variants in such genes are termed secondary findings and are an area of significant controversy. As the availability of genomic testing spreads and nongeneticist clinicians are able to order such testing, they must be aware of the potential for secondary findings and provide adequate counseling on this possibility.[15] The American College of Medical Genetics has a position statement on secondary findings that can guide clinicians.[39]

## When to Consider Clinical Genetic Testing

One approach to obtaining genetic testing for an individual is suggested in Fig. 3.3. First and foremost is clinical suspicion, primarily in cases in which the expression of disease seems out of proportion to what would be typically expected or when there is familial recurrence of an unusual phenotype. For example, severe, refractory RDS in a term or near-term infant should prompt consideration of a surfactant dysfunction disorder; recurrent sinusitis and respiratory infections should prompt consideration of primary ciliary dyskinesia (PCD); familial idiopathic pulmonary fibrosis should prompt consideration of telomerase or surfactant dysfunction.[40–44] As phenotype-associated gene panels continue to be developed, there will be less need for single gene testing and more reliance on panels that permit simultaneous sequencing of tens to hundreds of genes. The results are typically available within several weeks and often will afford the opportunity to intervene clinically.

WES/WGS

**FIG. 3.3** Suggested algorithm for considering genetic testing for an individual with lung disease. Clinical suspicion for a genetic disorder arises when expression of disease seems unusually severe or prolonged or when there is familial recurrence of an unusual phenotype. If the phenotype involves intellectual disability, other structural anomalies or multiple organ system involvement, then microarray analysis is the preferred first-line test. If the phenotype is recognizable or isolated to one organ system, single gene testing or a phenotype-specific gene panel should be considered. Patients who have a suspected genetic disorder despite a nondiagnostic preliminary evaluation should be considered candidates for whole exome or whole genome sequencing. Consultation

with clinical geneticists, genetic counselors, and laboratory-based geneticists can assist in selection of the appropriate testing options and interpretation of results. *NGS*, Next-generation sequencing; *WES*, whole exome sequencing; *WGS*, whole genome sequencing.

If the phenotype involves intellectual disability, other structural anomalies, or multiple organ system involvement, then microarray analysis is the preferred first-line test. Patients who have a suspected genetic disorder despite a nondiagnostic preliminary evaluation as described previously should be considered candidates for WES or WGS. Consultation with clinical geneticists, genetic counselors, and laboratory-based geneticists can assist in selection of the appropriate testing options. The website GeneTests.Org isa useful resource for identifying clinical laboratories thatare sequencing specific genes or panels of genes, thetesting approaches, and result reporting times (https://www.genetests.org).

## Research Study Designs to Attribute Genetic Variation to Disease

A variety of approaches, both from the standpoints of technology platforms for variant identification as well as methods for variant analysis, have been used to identify genetic associations with disease in cohorts of individuals, but there are several key features that are fundamental to any one approach. First, it is important to remember that most genetic association studies are simply that—associations of variants or genes with a particular phenotype. Identifying the direct mechanism by which a given variant results in a given phenotype requires functional studies, as mentioned previously. Second, understanding the advantages and limitations of the selected genetic testing approach is essential (outlined in Table 3.3), and third, having a statistically robust cohort size that is appropriate for the anticipated volume of data and the analytical approach will optimize the likelihood of detecting a genetic signal, should one exist. Fourth, careful attention must be paid to controlling for population stratification because some genetic variants are more common in some populations than others.

## Table 3.3

## Clinical Genetic Testing Methods

| Method | Characteristics | Advantages | Disadvantages | References |
|---|---|---|---|---|
| Karyotype | Microscopic examination of chromosomes: ~5–10 Mb[a] resolution | Speed (initial results within 48 h)<br>Detection of balanced translocations | Low resolution | 45 |
| FISH | Microscopic examination of selected locus/loci: ~50–250 kb[a] resolution | Speed (2–3 days)<br>Highly reliable coverage | Identifies copy number only at specified locus/loci | 46 |
| Chromosomal Microarray (SNP/Oligo) | Submicroscopic examination of copy number across genome: ~200–500 kb | Well-described coverage across genome<br>Ability to detect copy neutral changes with SNPs (e.g., uniparental disomy, loss of heterozygosity) | Longer turn around (can take 1–3 weeks)<br>Does not detect balanced translocation<br>Identifies copy number variants of unknown significance | 45 |
| Sanger Sequencing | Single gene sequencing | Long reads (>500 bp) | Does not scale well for multiple genes | 26,29 |
| MLPA | Submicroscopic detection of exon-level gains/losses by PCR-based assay | Reliable detection of exon-level copy number changes | Identifies copy number changes only at specified locus/loci | 47 |
| (NGS) Panel | High-throughput, massively parallel sequencing of multiple genes simultaneously | Cost-effective sequencing of 100s of genes simultaneously | Only sequences prespecified genes<br>Variants of unknown significance identified | 48 |
| WES | High-throughput, massively parallel sequencing of exons and flanking regions | Cost-effective sequencing of all known coding regions (~1% of genome) for detection of SNVs | Covers only ~1% of genome<br>Variable coverage of specific genes<br>Poor detection of non-SNV changes | 15 |

| | | | | |
|---|---|---|---|---|
| | | | Short reads (50–400 bp)<br>Variants of unknown significance<br>Incidental findings | |
| WGS | High-throughput, massively parallel sequencing across the genome | Cost-effective sequencing of whole genome<br>Detection of structural variants | Large informatics and data storage burden<br>Significant risk of variants of unknown significance being detected<br>Incidental findings | 15 |

[a] *Mb,* Mega basepairs; *kb,* kilo basepairs.

*FISH,* Fluorescent in situ hybridization; *MLPA,* multiplex ligation-dependent probe amplification; *NGS,* next-generation sequencing; *PCR,* polymerase chain reaction; *SNP,* single nucleotide polymorphisms; *WES,* whole exome sequencing; *WGS,* whole genome sequencing.

However, the single most important aspect of any genetic association study is defining phenotype. This is particularly challenging for pulmonary diseases because they generally are complex phenotypes, and there are likely to be multiple mechanisms, only some of which are genetic, that result in a single final common constellation of clinical symptoms, such as recurrent wheezing in asthma or need for supplemental oxygen after premature birth for BPD. Also a particular challenge for pulmonary disease is that very few objective, quantitative, minimally or noninvasive biomarkers for disease expression, such as the sweat chloride concentration for cystic fibrosis or nasal nitric oxide for PCD, are available, especially for diseases presenting in the newborn period or infancy. In addition, single gene defects may have pleomorphic presentations, such as children with pathogenic variants in the ATP-binding cassette member A3 *(ABCA3)* who might present in the neonatal period with severe neonatal respiratory failure or later in childhood with interstitial lung disease (see Chapters 54–57).[49] Alternatively, multiple genes might present with a similar constellation of symptoms, such as with PCD, for which pathogenic variants in more than 30 genes have been identified (Chapter 71).[42] These are just a few examples of phenotypic and genotypic variability that can complicate the search for the causative gene or genes. Thus, the more precisely a phenotype can be defined, the more homogeneous the study cohort can be to perform the appropriate association studies. One approach to increase the likelihood that a phenotype will capture variants of interest is to use an “extremes of phenotype” approach, which compares the individuals with the most severe presentations with the most “normal” controls, with the assumption that the affected individuals will be enriched for highly penetrant variants.[50,51] This approach was successful in using exome sequencing to identify *DCTN4* (dynactin subunit 4) as a modifier for early colonization with *Pseudomonas aeruginosa* in only 91 individuals with cystic fibrosis.[52]

The most traditional study designs to approach gene identification are family-based studies and case-control or cohort studies, thoroughly reviewed by Kosmicki et al.[53] Linkage mapping and family-based studies, which use patterns of allele sharing between individuals concordant for the disease, were the earliest techniques to localize large genomic regions associated with the disease. Traditionally, family-based tests require time-consuming pedigree analysis and recruitment of whole families, preferentially with multiple affected family members. However, with the availability of higher-resolution exome and genome-wide sequencing, a potential disease-causing *de novo* or transmitted variant can be identified using as few individuals as an affected child and parents (trio).[54]

The ability to interrogate regions across the genome using SNP arrays of 500,000 to 2 million known variants led to an expansion of GWAS that were applied to common, complex phenotypes, such as asthma and BPD. This was the application of the “Common Disease, Common Variant” hypothesis suggesting that risk for common diseases such as asthma or BPD is influenced by combinations of disease-predisposing alleles that are common in the population.[55–57] The underlying premise of GWAS is to compare frequencies of common variation across the genome (rather than a single gene) among diseased and healthy individuals for complex diseases. Taken together, GWAS have identified high-frequency variants with only modest associations and with inconsistent results across studies.[58] These variable results demonstrate (1) the challenges of phenotype and population selection, (2) the statistical challenges of assembling cohorts of sufficient size to detect a signal, and (3) the likelihood that these variants or regions are not linked mechanistically to the phenotype. Or if the variants or regions are linked, they explain only a small amount of the heritability and that other factors, including rare variants, gene × gene or gene × environment interactions may account for the missing disease heritability.[59] The National Human Genome Research Institute (NHGRI) and European Bioinformatics Institute (EBI) Catalog of Published Genome-Wide Association Studies provides an archive of more than 2400 published GWASs with more than 20,000 unique SNP-trait associations of $P < 10^{-5}$ (http://www.ebi.ac.uk/gwas/, accessed July 9, 2016).

The major limitation of the GWAS approach is that, because only known variants are interrogated, variant discovery, especially rare variants, is not possible. Sanger sequencing of candidate genes provides the opportunity to identify rare and novel variation in coding and noncoding regions, but it is time consuming, relatively expensive, and is typically used for small numbers of genes and for confirmation of high-throughput sequencing results. Now, exome or genome sequencing approaches are being more commonly applied to identify and incorporate rare variants into studies of complex phenotypes. There are significant limitations to these platforms as well, the major factor being cohort size coupled with the costs of sequencing and most importantly, the computational efforts for analysis of the massive volume of data that has to be reduced to manageable terms.[34] For example, in an exome sequencing study investigating genetic contributions to BPD in 100 infants, more than 55,000 high-confidence, nonsynonymous variants were identified.[60]

Therefore many assumptions that are based on the knowledge of the clinical and genetic epidemiology, hypothesized mechanisms for disease inheritance, and heritability are necessary to permit signals of potentially functional variants to emerge from the much larger group of variants that are likely to be inconsequential. As noted previously, GWAS assume that common variants either directly contribute to disease or tag other causative gene variants. Another approach is to assume that variants contributing to a disease are likely to be under negative selection pressure and are therefore rare. For example, Li et al., identified variants that were unique to a cohort of 100 babies with and without BPD, were not present in publicly available databases, such as ExAC, 1000 Genomes, or EVS (http://exac.broadinstitute.org/; http://www.1000genomes.org/; http://evs.gs.washington.edu/EVS/, respectively), and were postulated to be functional and to contribute to the phenotype.[60] They found more than 500 novel, nonsynonymous variants in more than 400 genes, which is still far too many for functional in vitro studies. Finally, the most agnostic approach is to not make any assumptions about rare versus common variants and include all in the analyses. Methods such as the fast family-based sequence kernel association test (FFB-SKAT) can include both common and rare variants and control for predicted magnitude of effect (relative weight) of each and other covariates, while also incorporating familial transmission.[61–63] Another common approach to further narrow down the variants or genes into more manageable units is to use pathway analysis, in which variants are grouped together into gene networks based on available literature about gene and protein interactions, most of which are derived from studies on cancer tissue.[64] However, these data are only as good as the published models, and many of the genes tend to participate in multiple pathways. The approaches to identify candidate variants and genes that are contributing to the phenotype and to predict the functional consequences of newly identified variants from these massive datasets are rapidly evolving and will become more reliable as new methodologies are developed.

## Epigenetics—Terminology and Technology

Epigenetics refers to modifications of the genome or gene expression that do not alter the underlying DNA sequence. For example, mammalian cells have identical DNA sequence, yet they are able to attain and maintain differentiated phenotypes. Because DNA sequence–based strategies do not account for the full heritability of complex traits or diseases, epigenetic mechanisms may contribute to missing disease heritability and are significant components of the "environmental" and "developmental" aspects of the gene × environment × development triad (see Fig. 3.1).[65] Epigenetic modifications are influenced by environmental stimuli, including infection, oxidative stress, and aging/development.[66] The three major types of epigenetic modifications, DNA methylation, histone modifications, and noncoding RNAs, are briefly reviewed here.

DNA methylation refers to the addition of a methyl group to the 5-carbon of the cytosine ring, usually in the context of CpG dinucleotides or islands (Fig. 3.4). Mediated by DNA methyltransferases (DNMTs), this highly stable, covalent modification leads to tight packing of DNA and histones and generally results in transcriptional silencing.[67] Most human gene promoters contain CpG islands and are generally unmethylated in normal cells, although they can become methylated during tissue-specific development.[68] Methylation of promoter regions inhibits gene expression by directly preventing transcription factor binding or indirectly by facilitating the binding of methyl-CpG-binding proteins, which then inhibit transcription factor binding.[69] Several studies have identified alterations of DNA methylation patterns among genes important in fibrosis among individuals with idiopathic pulmonary fibrosis.[70,71]

**FIG. 3.4** Depiction of epigenetic changes through DNA methylation and histone modification. (A) DNA is wrapped around the nucleosome, which is made up of core histones H2A, H2B, H3, and H4. The free ends of histone tails may undergo posttranslational modifications (e.g., acetylation, phosphorylation, and methylation) that influence the configuration of chromatin. Opened states (euchromatin) allow transcription, whereas closed states (heterochromatin) restrict transcription. (B) Euchromatin is characterized by acetylation and phosphorylation *(purple polygons)*, whereas methylation *(yellow circles)* is more often found at heterochromatin. Specific histone modifications and DNA methylation reciprocally influence each other. For example, histone methylation at H3K9, H3K27, and H4K20 promotes DNA methylation at CpG dinucleotides. This covalent modification results in the transfer of a methyl group *(red circles)* to cytosine residues at gene regulatory regions. Hypermethylation typically results in transcriptional repression, whereas hypomethylation facilitates gene transcription. (Modified with permission from Raabe FJ, Spengler D. Epigenetic risk factors in PTSD and depression. *Front Psychiatry.* 2013. http://dx.doi.org/10.3389/fpsyt.2013.00080 License: https://creativecommons.org/licenses/by/3.0/.)

Histones are small, positively charged proteins with an affinity toward negatively charged DNA.[69] In the nucleus, DNA is wrapped around histones and organized into nucleosomes, which condense to form chromatin. Euchromatin is loosely packed and transcriptionally active, whereas heterochromatin is tightly packed and transcriptionally inactive (see Fig. 3.4). Histones are subject to posttranscriptional modifications, including acetylation, methylation, phosphorylation, ubiquitination, and small ubiquitin-like modifier (SUMO)ylation, which result in structural and functional changes that can alter gene transcription, DNA repair and replication, splicing, and chromosome condensation.[72–75] Acetylated and phosphorylated histones typically indicate transcriptionally active states, whereas methylated histones typically indicate repressed/inactive heterochromatin. Changes in histone modifications alter expression of genes important in the pathogenesis of idiopathic pulmonary fibrosis, and inhibition of histone deacetylators has been proposed as a potential therapy for fibrotic lung diseases.[76–79]

In addition to coding RNAs that are translated into proteins, the eukaryotic genome transcribes a large number of noncoding RNAs that are functional molecules that largely regulate gene transcription, posttranscriptional modifications, and translation.[66] Transfer RNA (tRNA) and ribosomal (rRNA) are well-described noncoding RNAs that are essential for protein synthesis. Small (approximately 20–30 nucleotides) noncoding RNAs, including microRNA (miRNA), short interfering RNA (siRNA), and piwi-interacting RNA (piRNA), regulate gene expression through chromatin structure, RNA processing and stability, and translation. Although siRNAs target specific mRNAs, miRNA can target multiple genes and gene pathways as well as proteins. Decreased expression of a microRNA cluster (miR17–92) required for normal lung growth and development was observed in autopsy specimens from infants with BPD.[80] Long (>200 nucleotides) noncoding RNAs are also thought to play a role in chromatin remodeling, transcription, posttranscriptional processing, intracellular trafficking, and imprinting.[81–83] Disruption of genomic regions encoding long noncoding RNAs that regulate expression of *FOXF1* has been identified among infants with alveolar capillary dysplasia with misalignment of the pulmonary veins.[84]

The contributions of epigenetic modifications to human disease processes are emerging and may account for a portion of disease heritability. Whole genome, high-resolution maps for epigenetic modifications are emerging and comparison of profiles in healthy and diseased individuals and tissues may identify novel disease mechanisms and therapies.[85]

## "Multi-Omics" Approaches to Refine Genotype-Phenotype Associations

The availability of high-throughput sequencing has also permitted in-depth identification of microbial elements of the so-called microbiome, including bacteria, viruses, and fungi, that provide important homeostatic functions for the body but also may influence the development of disease.[86] The complex interactions between the microbiome and host immune effector cells are not well understood. In the case of the lung the microbiota may not only modulate local immune regulation, but distant interactions with the gastrointestinal tract may actually be more important in development of local and systemic immunity, the so-called "lung-gut axis."[87,88]

Based on the complexity of assessing contributions of genes, environment, and development to complex phenotypes, it is clear that no single approach is sufficient to determine mechanisms of disease. With the development of high-throughput platforms for not only DNA and RNA sequencing and epigenetic changes, but also mass spectrometry for protein, lipid, and metabolite analysis, other approaches that integrate these multiple "omics" platforms, including genomics, transcriptomics, epigenomics, proteomics, lipidomics, and metabolomics, will help to derive high-resolution, mechanistic phenotype classifications.[89–93]

The key to integrating all these approaches will be the development of computational capabilities to model systems biology and reduce the volume of data to manageable datasets upon which hypothesis-driven functional studies can be developed. However, the ultimate goal will be to tailor therapeutic interventions to the individual's mechanism(s) of disease and anticipated responses to those interventions—"precision medicine."[94] This approach to treating individual patients will require the coordination of basic scientists, bioinformaticians, geneticists, clinicians, and bioethicists to acquire and interpret the data, define treatment, and counsel the family regarding not only the treatment decisions but also the implications of the diagnosis for the entire family.

# Environmental Contributions to Respiratory Disease in Children

*Peter Sly MBBS, MD, FRACP, DSc, Andrew Bush MB BS(HONS), MA, MD, FRCP, FRCPCH, FERS*

Progress towards meeting the eight United Nations Millennium Development Goals has been accompanied by a substantial change in the global pattern of disease, with a significant shift towards chronic noncommunicable diseases (NCDs). Globally, early childhood deaths have declined, but years lived with disability have increased over the 20 years 1990–2010: cardiovascular disease by 17.7%; chronic respiratory disease by 8.5%; neurologic conditions by 12.2%; diabetes by 30.0%; and mental and behavioral disorders by 5.0%.[1] These trends are continuing with further increases in the global burden of disease related to chronic NCDs reported in the 2013 updates.[2,3] There is increasing recognition that many chronic diseases are initiated in early life.[4] This chapter will review the role that environmental exposures, especially those occurring in early life, play in increasing long-term risk of respiratory disease.

# Vulnerability of Children to Adverse Environmental Exposures

In pediatrics the statement that “children are not little adults” is well known and understood. Children are in an active anabolic state as they grow and, as such, have increased requirements for air, water, and food, relative to their body size. This translates into a higher minute ventilation in liters/kg/day, increased maintenance requirements of calories (cal/kg/day) and water (mL/kg/day), especially during infancy and early childhood.[5] In addition, children interact with their environment in ways that adults do not. Young children spend more time on the floor, where the concentration of environmental toxicants is higher. They are also more likely to put hands, feet, and objects into their mouths and noses and to ingest more toxicant-containing dust.[5] Children also have different exposure pathways than adults (Table 4.1). Taken together, these factors result in children receiving a larger dose of toxicants in any given environment than an adult in the same environment.

## Table 4.1

### Exposure Pathways for Environmental Exposures at Different Ages

| Pathway | Prenatal | Infant | Child | Adolescent | Adult |
|---|---|---|---|---|---|
| Transplacental | √ | | | | |
| Breast milk | | √ | | | |
| Nutritive ingestion | | √√√ | √√ | √ | √ |
| Nonnutritive ingestion | | √√ | √√√ | √ | √ |
| Inhalation | | √√√ | √√ | √ | √ |
| Transdermal | | √√√ | √√ | √ | √ |
| Risk-taking behavior | | | √ | √√√ | √ |

Transplacental transmission is an exposure pathway that is not always taken fully into account when considering the impact of environmental exposures on increasing long-term disease risk. Previously, there was a view that the placental “barrier” protected the developing fetus from maternal exposures. However, we now know that many xenobiotics pass directly through the placenta[6,7] and that maternal exposure during pregnancy can adversely affect fetal outcomes and increase long-term disease risk. Breast milk is another exposure pathway that is not always considered. Although breast milk is the ideal food for human newborn infants, the milk can contain a variety of environmental toxicants, including persistent organic pollutants, pesticides, heavy metals, plasticizers, and other chemicals[8,9] that can increase disease risk.

Children are likely to be exposed to environmental toxicants in a number of different settings, depending on their age. Infants and young children will be exposed primarily in their home, whereas older children are likely to also be exposed in the local neighborhood, at daycare or school, and in the wider environment. Sources for common environmental exposures within the home are shown in Table 4.2.

## Table 4.2

## Common Environmental Exposures Encountered in a Home Environment

| **Toxicant** | **Matrix** | **Source** | **Route of Exposure** |
|---|---|---|---|
| Flame retardants | Dust, air, breast milk, food | Furnishings, clothing, electronic equipment | Nutritive and nonnutritive ingestion<br>Inhalation, dermal |
| Pesticides | Air, dust, breast milk, food and beverages | Pest control sprays, agricultural practices, house and garden insecticides | Nutritive and nonnutritive ingestion<br>Inhalation, dermal |
| Plastics/plasticizers | Food and beverages, air | Food containers (especially when heated) cosmetics, personal care products | Nutritive ingestion, dermal, inhalation |
| Combustion-related products (particulates, gaseous pollutants, polyaromatic hydrocarbons) | Air, dust | Cigarettes, candles, mosquito coils, biomass fuel, gas cooking | Inhalation, nonnutritive ingestion, dermal |
| Volatile organics | Air, dust | Furniture, building materials, glues, carpets, cigarettes, mosquito coils, personal care products | Inhalation, nonnutritive ingestion, dermal |
| Perfluorinated compounds | Food, water, dust | Teflon-coated cookware, industrial contamination of water | Nutritive and nonnutritive ingestion, inhalation, dermal |

In addition to receiving a higher dose of toxicant in any given environment, infants and young children are less able to metabolize and detoxify xenobiotics. Phase I (cytochrome P450 enzymes) and II (antioxidant defense) metabolic enzymes are immature at birth and mature relatively slowly after birth.[5] This is likely to mean that the adverse effect of the increased dose received will be magnified by the young child's inability to handle the toxicant.

Although many organ systems are essentially mature at birth, this is not true for the respiratory, immune, and central nervous systems. Thus these organ systems are vulnerable to both prenatal and postnatal environmental exposures. From the point of respiratory disease the vulnerability of both the respiratory and immune systems is of concern. Although a full description of the developmental profiles of the respiratory and immune systems is beyond the scope of this chapter, a brief overview is warranted. The airway branching tree develops between approximately 6 and 16 weeks' gestation during the pseudoglandular phase of lung development. Thus environmental exposure that influences the structural development of the airways must occur during this window of susceptibility. Maternal exposure to air pollution and maternal smoking during pregnancy are two such exposures. However, environmental exposures occurring after this time, most notably ozone, can result in thicker airways and heightened responsiveness to constrictor stimuli after birth. Alveolar development begins later, at around 24 weeks' gestation and is not complete at birth but continues in the early postnatal period. Although it is not known with certainty when alveolar development stops, the lung is especially vulnerable to environmental exposures occurring during the first 18–24 months of postnatal life.[5] Similarly, both the innate and adaptive arms of the immune system are immature at birth and mature postnatally under the influence of environmental cues.[10] As will be discussed later, delayed maturation of the immune system increases the risk of respiratory infections and asthma.

From a global perspective, socioeconomic factors such as poverty and poor nutrition can magnify the effects of adverse environmental exposures and increase disease risk. Poor nutrition includes both undernutrition resulting in stunting and inappropriate nutrition with high-calorie processed food resulting in obesity. Although this is especially true in low- and middle-income countries, it is also true in high-income countries where social disparities exist.[11–15] Poverty, poor housing, poor nutrition resulting in trace element deficiency, stunting and underweight, excess noise, and emotional/physiologic stress are likely to increase disease risk from a given environmental exposure. Thus in determining with certainty the likely adverse health risk from adverse environmental exposures, one must consider: the developmental stage of the child (prenatal, infant, child, etc.); the social circumstances in which the exposure occurs; and the type and route of exposure. For multiple reasons outlined previously, one cannot extrapolate the risk from, or consequences of, exposures from adults to children.

## Mechanisms Underlying the Increased Disease Risk From Adverse Environmental Exposures

Epidemiologic studies suggest that a wide variety of environmental exposures in early life can increase long-term disease risk. For example, exposure to traffic-related air pollution has been independently linked to: reduced fetal growth; premature birth; lower lung function at birth; increased respiratory infections; decreased lung function growth during childhood; incident asthma; an increased risk of chronic obstructive pulmonary disease (COPD); lung cancer; as well as obesity, type 2 diabetes, and cardiovascular disease.[16,17] Other environmental exposures are also related to a wide range of outcomes suggesting that common mechanisms are likely to link such exposures to disease outcomes. Potential mechanisms will be discussed in the next sections.

### Individual Susceptibility, Gene by Environmental Interactions, and Epigenetic Mechanisms Contributing to Respiratory Disease in Children

Being exposed to adverse environmental exposures does not, by itself, confer an increased risk of disease. Not all smokers develop lung cancer or COPD; however, some individuals are more susceptible than others. This suggests that individual susceptibility related to genetic variations is likely to be important.

There is increasing evidence that many of the risk factors for respiratory disease have a genetic contribution that may underlie individual susceptibility. Low lung function is a primary risk for both acute respiratory disease in early life and chronic respiratory disease throughout life. Several genetic variations have been associated with low lung function, reduced lung function growth, or accelerated lung function decline.[18–21] Similarly, genetic variations have been associated with an increased susceptibility to lower respiratory infections,[22–24] delayed maturation of the immune system, and early allergic sensitization.[10,25] Genetic variations in the body systems designed to defend against environmental exposures, such as the antioxidant defense system, have also been reported as increasing individual susceptibility to respiratory disease,[26] especially with exposure to traffic-related air pollution.[27] Fig. 4.1 gives a schematic representation of the multiple pathways increasing disease risk in which individual susceptibility related to genetic variation has been reported. These same pathways are also susceptible to environmental exposures, opening the way to environmentally induced epigenetic processes and gene × environment interaction. Although a full description of all of these pathways is beyond the scope of this chapter, several warrant further discussion.

### Epigenetic Mechanisms Increasing the Risk of Disease.

Despite a clear genetic component to asthma susceptibility—everyone knows that asthma runs in families—the failure of genetic studies, either candidate gene or genome-wide association studies, to explain more than a fraction of asthma has prompted investigation of other means by which gene variation and dysfunction could be involved.[28] Many have turned to the study of epigenetics and global methylation. Epigenetics refers to the process whereby gene expression and function is altered without altering the DNA sequence of the gene. Several epigenetic mechanisms have been described, including DNA methylation at cytosine-guanine dinucleotide (CpG) residues, posttranslational modification of nuclear histones, and noncoding RNA-mediated gene silencing.[28,29] These changes in gene function can survive cell division and can be heritable,[29] although this is perhaps not as common in mammals as sometimes suggested because global demethylation and germline reprogramming limit transgenerational inheritance of epigenetic marks.[30] DNA methylation changes throughout life,[31] especially in key windows of vulnerability, but much of the epigenome is established during fetal development and provides a mechanism by which prenatal environmental exposures can increase disease risk.[29] Maternal smoking during pregnancy has negative impacts on fetal lung development, immune system development, and somatic growth (as well as on neurodevelopment) that increase the risk of respiratory disease throughout life.[32–34] Although direct data are scarce, epigenetic mechanisms are widely thought to be involved.[28,29,35–37] Third-generation effects in which an increased asthma risk from grand-maternal smoking is passed to grandchildren via mothers exposed in utero is also thought to occur via epigenetic mechanisms.[38] A likely mechanism by which environmental exposures such as tobacco smoke, household air pollution (especially biomass fuel burning), traffic-related pollution, and household chemicals can induce adverse changes in the epigenome that increase disease risk is by causing oxidative stress in the mother during pregnancy, potentially through upregulating expression of proinflammatory genes by histone modification and chromatin remodeling.[35] Individual susceptibility to oxidative stress is increased by genetic variations in antioxidant defense genes.[39–41]

Data showing that maternal factors can influence oocyte development and transfer disease risk to offspring via mitochondrial transfer present another mechanism for environmental exposures to increase disease risk. Mitochondrial transfer from mesenchymal stromal (stem) cells to injured cells has been well established in the lungs.[42,43] More recently, Wu and colleagues[44] have shown that oocytes from obese mice produce heavier fetuses when transferred to lean recipients; direct mitochondrial transfer from oocytes to blastocysts was the proposed mechanism. These data raise the probability that other environmental exposures prior to conception can modify oocytes by mechanisms other than epigenetics and suggest that more attention should be paid to the health of girls and young women to reduce NCDs.

### Antioxidant Defense.

As outlined previously, antioxidant defense plays a substantial role linking environmental exposures to disease risk. Fig. 4.2 gives a schematic representation of the genetic and epigenetic mechanisms and the environmental exposures increasing disease risk when antioxidant defenses are inadequate.

## Microbial Recognition.

We are all exposed to microbes and microbial products in our environment. Such exposures are critical for postnatal maturation of the innate and adaptive limbs of the immune system and for decreasing risk of respiratory disease.[45,46] The interplay between resident bacteria and the immune system at times of respiratory viral infections in early life is also likely to have a significant influence on later risk of respiratory disease.[47] Thus genetic and environmental influences on microbial recognition of microorganisms are another potentially critical factor likely to influence disease risk. Fig. 4.3 shows a schematic representation of such interactions.

## Allergic Inflammation.

Allergic sensitization in early life is a major risk factor for persistent asthma,[25] with the risk of sensitization being altered by genetic and epigenetic mechanisms and environmental exposures. In general, low-dose allergen exposure increases the risk of allergic sensitization, whereas high-dose favors the development of immune tolerance and not sensitization,[48] especially in the presence of high concentrations of microbial products.[45,49,50] However, environmental exposures also have the potential to alter genetic responses and modify the risk of allergic sensitization.[51–53] One particular environmental exposure that has the potential to modify the risk of allergic sensitization is exposure to microbial products, including lipopolysaccharide (LPS). Exposure to microbial-rich animal barn dust during fetal development and early life has been shown to protect against allergic sensitization.[54] However, the protection depends on the level of LPS exposure and genetic variations in the CD14 gene, with the C allele at CD14/-159 increasing the risk of allergic sensitization in the presence of low LPS levels and the T allele increasing risk with high levels of LPS.[55] Other genetic variations can also play a role, with the A20 protein, a transcription product of TNFAIP3, in airway epithelial cells mediating LPS-induced attenuation of house dust mite allergen–induced inflammatory responses.[45]

Fig. 4.4 shows a schematic representation of environmental, genetic, and epigenetic factors influencing the risk of allergic sensitization in early life. Whether these pathways increase the risk for other respiratory diseases is less certain, but possible, especially COPD, in which early life exposures do increase risk.[56,57]

## Low Lung Function/Reduced Lung Growth, Delayed Immune Maturation, and Somatic Growth Restriction Predisposing to Respiratory Disease

Low lung function is a risk factor for all respiratory diseases, both acute and chronic, throughout all stages of life. The respiratory system is not mature at birth because at least half of the adult complement of alveoli developing postnatally. The lungs are vulnerable to both prenatal and postnatal environmental insults that can limit lung function and lung function growth.[17,56,57] Lung function "tracks" postnatally, meaning that lung function at birth is a major determinant of lung function throughout life[17,56,57]; however, severe respiratory infections and adverse environmental exposures can reduce lung function growth,[27,33,58–62] resulting in a reduction in lung function that should have been gained. Fig. 4.5 shows a schematic representation of the interrelationships between prenatal and postnatal exposures increasing the risk for respiratory diseases in later life.

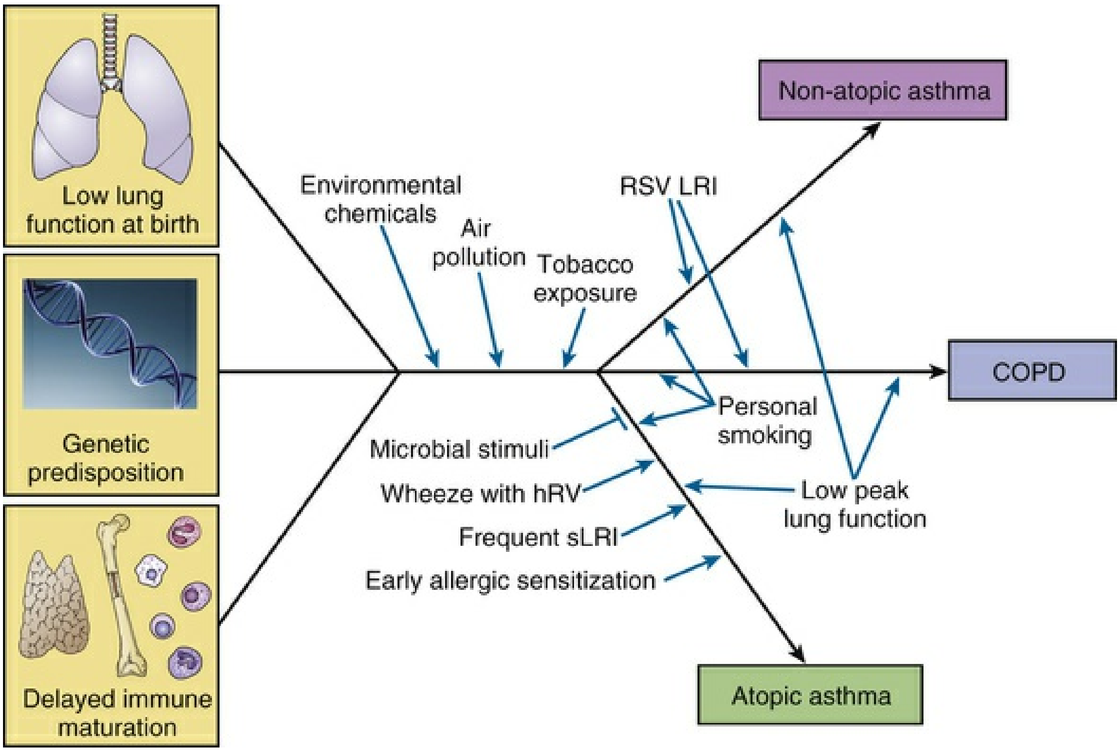
COPD

**FIG. 4.5** Schematic representation of how environmental exposures increase the risk of respiratory diseases. *ARI,* Acute respiratory infection; *COPD,* chronic obstructive pulmonary disease; *ETS,* environmental tobacco smoke.

Prenatal exposures can increase the risk of postnatal respiratory disease by reducing lung function at birth, reducing somatic growth, or delaying immune system maturation during fetal development. Many exposures have more than one effect, possibly by epigenetic alteration of gene function as discussed previously. Maternal smoking during pregnancy increases the risk for all respiratory diseases by causing reduced lung function at birth,[63] low birth weight,[64,65] and delayed immune maturation.[34] Similarly, maternal exposure to higher levels of ambient air pollution has been associated with lower birth weight, reduced lung function, and delayed immune maturation.[16,17,61,66] An increasing range of prenatal environmental exposures are being linked to risk of respiratory disease, especially wheezing in early childhood and persistent asthma. However, for many of these the mechanisms are uncertain and not all studies show strong associations, Further research with both improved exposure assessments and outcome measurements is required.

## Common Pathways to Respiratory Diseases

Debate continues about whether the various chronic respiratory diseases are different entities or components of a single disease spectrum.[67] Holt and Sly[68] postulated that atopic asthma, nonatopic asthma, and COPD could be part of a "family tree" of respiratory diseases stemming from a common origin but subject to environmental exposures occurring at different times during postnatal development and with differing frequency and severity. Fig. 4.6 shows a schematic representation of the common susceptibilities and exposures that could lead to atopic asthma, nonatopic asthma, and COPD.



Low lung function at birth

Wheeze with hRV
Frequent sLRI
Early allergic sensitization
Atopic asthma

**FIG. 4.6** Schematic representation of the "Family Tree" of respiratory diseases. *COPD,* Chronic obstructive pulmonary disease; *hRV,* human rhinovirus; *LRI,* lower respiratory illness; *RSV,* respiratory syncytial virus; *sLRI,* severe lower respiratory illness associated with fever and/or wheeze. (Holt P, Sly P. Non-atopic intrinsic asthma and the 'family tree' of chronic

respiratory disease syndromes. *Clin Exp Allergy.* 2009;39:807-811.)

Low lung function at birth and low lung growth during childhood is likely to increase the risk of both acute and chronic respiratory diseases. Low lung function at birth increases the risk of acute respiratory illness (ARI) and pneumonia in early life,[10,57,69] asthma, and COPD.[10,56,61,69,70] Environmental insults, especially those occurring in the first 2–4 years during the period of rapid lung growth, can decrease lung growth.[12,17,27,33,56,59–61,69–74] Similarly, severe lower respiratory illnesses (sLRIs) and pneumonia in early life can reduce lung growth.[75] Lung function “grows” to reach a peak in early adult life, remains at a plateau for some years, and then begins to decline. Much of the rate of decline is under genetic control but can also be accelerated by smoking and in those exposed to adverse environmental exposures in early life.[76–78] Failure to reach the peak lung function that would be predicted by parental and genetic factors increases the risk of developing respiratory symptoms and COPD in later life. A compilation of data from three large adult cohorts estimated that approximately half of those developing COPD did so because they had a reduced peak lung function and half developed COPD due to an accelerated rate of lung function decline.[70] Thus preventing low lung function at birth and preserving lung function growth during childhood is of the utmost importance in preventing chronic lung disease.

## Environmental Contributions to Acute Respiratory Illness and Pneumonia

As outlined in the previous sections, environmental exposures increase the risk of ARI and pneumonia in early life. However, what is less certain is which exposures increase the primary risk (i.e., without which the disease is less likely to occur) as opposed to factors with increase the severity of the disease. To some extent this distinction is artificial but does have implications for disease prevention. Prenatal exposures increasing disease risk may be primary risk factors. These exposures include: maternal smoking during pregnancy,[79] maternal infections, especially HIV[79]; maternal exposures to arsenic[80,81]; and maternal exposure to ambient or household air pollution resulting in lower lung function at birth (see earlier). Exposures that occur both prenatally and postnatally, such as exposure to increased levels of particulate matter in both indoor and ambient environments,[82–85] tobacco smoke exposure,[79,86] poor household ventilation, and overcrowding,[79,84,87] may have primary effects either prenatally or postnatally but may also act to increase illness severity in those young children contracting respiratory viral or bacterial infections. Evidence is increasing that the components of the infant's respiratory microbiome in the upper airway and gastrointestinal system can either increase or decrease risk of ARI, especially at times of respiratory viral infections.[79,84,87] Childhood malnutrition, stunting, and living in poor circumstances are likely to both increase disease risk and severity.[84,85,87–89]

One environmental factor that is frequently overlooked is climate, including humidity, hours of sunshine, temperature, rainfall, and related factors.[90,91] Whether the climate-related factors increase the risk of ARI by increasing viral survival and transmission efficiency or by causing seasonal variations in immunocompetence through nutritional or vitamin D–related pathways is not known.[90–97] However, the influence of global climate change is likely to increase the prevalence and severity of ARI in children.

## Environmental Contributions to Asthma

Asthma can be considered to be a developmental disease, where the normal growth and development of the respiratory and immune systems are modified by both genetic and environmental factors that result in altered lung structure and function, increased susceptibility to respiratory infections and allergic sensitization early in life.[10] Both the respiratory and immune systems are vulnerable to adverse environmental exposures occurring both before and after birth. Although most asthma develops in childhood, incident asthma does occur in adults. Thus an understanding of the environmental contributions to asthma across all stages of life is important.

Again, understanding of environmental factors that increase the risk of developing asthma (i.e., asthma inception) is important. The same exposures occurring in a child who already has asthma may also increase the likelihood of having symptoms, increase the severity of symptoms, or trigger acute exacerbations of asthma. An overview of the environmental factors involved in inception or triggering of asthma is shown in Tables 4.3 and 4.4.

## Table 4.3

## Environmental Exposures Associated With Inception of Asthma at Different Life Stages

| **Exposure** | **Life Stage of Exposure** | | | | |
| | **Preconception** | **Fetal Development** | **Infancy** | **Childhood** | **Adol** |
| Tobacco smoke | Grand maternal smoking imposes risk via maternal oocytes[38] | ↓Lung function, ↓Birth weight, ↑BHR,[33,63] delayed immune maturation[34] | ↓Lung growth,[65,98–100] ↑ARI[100,101] | ↓Lung growth,[58,98,102–105] ↑BHR,[32,33] ↑ARI[58,98,102–105] | ↓Lun<br>↑BHR |
| Indoor air pollution | N/S | ↓Lung function, ↓Birth weight[106] | ↓Lung growth, ↑ARI[12,106–108] | ↓Lung growth, ↑ARI[12,106,109] | ↓Lun<br>girls[11 |
| Ambient air pollution | N/S | ↓Lung function[69,113], ↓Birth weight[64] | ↓Lung growth, ↑ARI[59,60] | ↓Lung growth, ↑ARI[17,27,59,60,69,114,115] | ↓Lun<br>functi |
| PCBs | N/S | ↓Birth weight[116] | ↑ARI[117] | ↑ARI[117] | N/S |
| Bisphenols/phthalates | N/S | ↓Birth weight[118] | ↑Wheeze[119] | ↑Wheeze, ↓Lung function[120] | N/S |
| Household chemicals | N/S | ↓Birth weight[121] | ↑Wheeze[121] | ↑Wheeze, ↓Lung function[121] | N/S |
| Bioaerosols | N/S | May be protective[49] | High dose protective, low dose ↑allergy[48] | High dose protective, low dose ↑allergy[48] | N/S |

*AHR*, Airway hyperresponsiveness; *ARI*, acute respiratory infections; *N/S*, not studied; *N/A*, not applicable; *PCBs*, polychlorinated biphenyls.

## Table 4.4

## Environmental Exposures Associated With Triggering of Asthma

**Asthma Triggering**

| Exposure | Life Stage of Exposure | | | | |
|---|---|---|---|---|---|
| | Preconception | Fetal Development | Infancy | Childhood | Adoles |
| Tobacco smoke | N/A | N/A | ↑Wheeze,<br>↑ARI[17,58,102] | ↑Wheeze,<br>↑ARI[17,58,86,102] | ↑Whee<br>↑ARI[17, |
| Indoor air pollution | N/A | N/A | ↑Wheeze,<br>↑ARI[15,122] | ↑Wheeze,<br>↑ARI[15,84,87,102] | ↑Whee<br>↑ARI[12 |
| Ambient air pollution | N/A | N/A | ↑Wheeze,<br>↑ARI[17,115] | ↑Wheeze, ↑ARI,<br>↑BHR[17,59,115,123–125] | ↑Whee<br>↑ARI,<br>↑BHR[17 |
| PCBs | N/A | N/A | ↑Wheeze,<br>↑ARI[117] | ↑Wheeze,<br>↑ARI[117] | N/S |
| Bisphenols/phthalates | N/A | N/A | N/S | ↑Wheeze,<br>↑BHR[127] | N/S |
| Household chemicals | N/A | N/A | ↑Wheeze[121] | ↑Wheeze[121] | N/S |
| Bioaerosols | N/A | N/A | ↑Wheeze[128,129] | ↑Wheeze, acute asthma[128,129] | ↑Whee<br>acute<br>asthma |

*AHR,* Airway hyperresponsiveness; *ARI,* acute respiratory infections; *BHR,* bronchial hyperresponsiveness; *N/S,* not studied; *N/A,* not applicable; *PCBs,* polychlorinated biphenyls.

# Summary

Environmental exposures, especially those occurring during fetal development and in early postnatal life, increase the risk of acute and chronic respiratory diseases. Many of these exposures are avoidable and provide an opportunity to prevent or reduce the burden of respiratory diseases.

# The Surfactant System

*Paul Kingma MD, PhD, Alan H. Jobe MD, PhD*

Pulmonary surfactant is a complex substance with multiple functions in the microenvironments of the alveoli and small airways.[1] The traditional functions of surfactant are the biophysical activities to keep the lungs open, to decrease the work of breathing, and to prevent alveolar edema. Most of the components of surfactant also contribute to innate host defenses and injury responses of the lung.[2] Surfactant deficiency states occur with prematurity and with severe lung injury syndromes. Recent studies in humans and in mice have defined an expanding number of genetic and metabolic abnormalities that disrupt surfactant and cause lung diseases, which range from lethal respiratory failure at birth to chronic interstitial lung disease in later life.[3] We will summarize those aspects of surfactant biology that are relevant to children.

## Surfactant Composition and Metabolism

### Composition

Surfactant recovered from lungs by bronchoalveolar lavage contains about 80% phospholipids, about 8% protein, and about 8% neutral lipids, primarily cholesterol (Fig. 5.1).[4] The phosphatidylcholine species of the phospholipids contribute about 70% by weight to surfactant. The phospholipids in surfactant are unique relative to the lipid composition of lung tissue or other organs. About 50% of the phosphatidylcholine species have two palmitic acids or other saturated fatty acids esterified to the glycerol-phosphorylcholine backbone, resulting in "saturated" phosphatidylcholine, which is the principal surface-active component of surfactant. About 8% of surfactant is the acidic phospholipid phosphatidylglycerol. Surfactant from the immature fetus contains relatively large amounts of phosphatidylinositol, which then decreases as phosphatidylglycerol appears with lung maturity.[5]

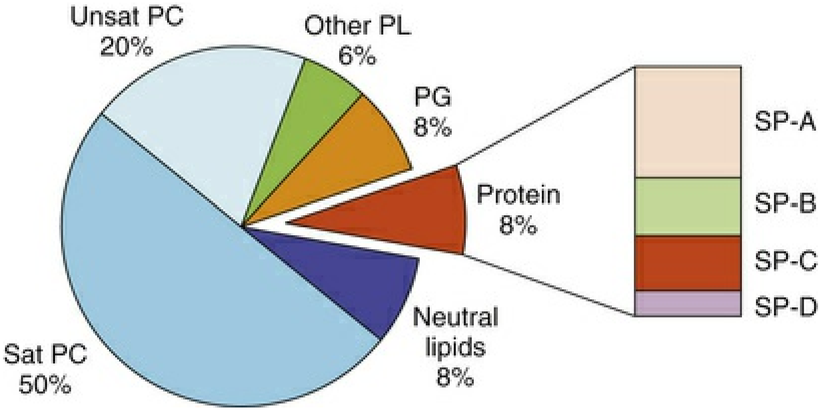

**FIG. 5.1** Composition of surfactant. Saturated phosphatidylcholines (PC) are the major components of alveolar surfactant. Minor lipid components include unsaturated PC, phosphotidylglycerol (PG), neutral lipids, and other phospholipids (PL). The proteins contribute about 8% to the weight of surfactant. *SP-A,* Surfactant protein A; *SP-B,* surfactant protein B; *SP-C,* surfactant protein C; *SP-D,* surfactant protein D.

Four primary surfactant-associated proteins have been identified: A, B, C, and D.[6,7] Initial analyses of these proteins suggested that the hydrophilic surfactant protein A (SP-A) and surfactant protein D (SP-D) were primarily involved in pulmonary innate immunity, whereas the hydrophobic surfactant protein B (SP-B) and surfactant protein C (SP-C) facilitated surfactant lipid physiology. However, we now know that the surfactant proteins often cross these lines of functional classification.

SP-A and SP-D are members of the collectin family of innate defense proteins. Collectins are defined by four structural domains shared by all family members: a short amino-terminal cross-linking domain, a triple helical collagenous domain, a neck domain, and a carbohydrate recognition domain (CRD).[6–10] Three neck domains combine and facilitate the formation of a collagen-like triple helix that then aggregates to form larger multimers of the collectin trimer. SP-A is a 24-kD monomer that further assembles to a bouquet of six trimers with a molecular size of 650 kD.[11–13] SP-A is encoded by two genes located within a “collectin locus” on the long arm of chromosome 10 that also includes the genes for SP-D and the mannose binding protein.[14] In humans, SP-A synthesis begins during the second trimester of gestation and occurs primarily in the alveolar type II epithelial cells, club cells, and in cells of tracheobronchial glands. SP-A is required for the formation of tubular myelin and has several roles in pulmonary host defense.

SP-D is a 43-kD hydrophilic collectin with a monomer structure that is similar to SP-A, although the collagen domain of SP-D is much longer.[13,15] Structural studies demonstrate that SP-D trimers further combine into larger multimeric complexes through N-terminal interactions that are stabilized by N-terminal disulfide bonds.[8,12,16] Although larger, more complex forms have been identified, SP-D exists predominately as a tetramer of trimeric subunits (dodecamer) assembled into a cruciform. SP-D is synthesized by type II cells and by club cells, as well as in other epithelial sites. Like the other surfactant proteins, SP-D expression is developmentally regulated and induced by glucocorticoids and inflammation.[17] In addition to the complex roles of SP-D in pulmonary host defense, SP-D also influences surfactant structure and is required for surfactant reuptake and the regulation of pulmonary surfactant pool sizes.[18,19]

SP-B is a small hydrophobic protein that contributes about 2% to the surfactant mass.[1,6] The SP-B gene is on human chromosome 2 and is expressed in a highly cell-specific manner. The primary translation product is 40 kD, but the protein is clipped in the type II cell to become an 8-kD protein prior to associating with phospholipids during the formation of lamellar bodies. SP-B facilitates the surface absorption of lipids into the expanding alveolar surface film and enhances their stability during the movements of the respiratory cycle. A genetic lack of SP-B causes a loss of normal lamellar bodies in type II cells, a lack of mature SP-C, and the appearance of incompletely processed SP-C in the airspaces.[20]

The SP-C gene is on chromosome 8, and its primary translation product is a 22-kD protein that is processed to an extremely hydrophobic 35 amino acid peptide rich in valine, leucine, and isoleucine.[21] The SP-C gene is expressed in cells lining the developing airways from early gestation. With advancing lung maturation, SP-C gene expression becomes localized only to type II cells. SP-B and SP-C are packaged together into lamellar bodies and function cooperatively to optimize rapid adsorption and spreading of phospholipids. Surfactants prepared by organic solvent extraction of natural surfactants or from lung tissue contain SP-B and SP-C. Such surfactants are similar to natural surfactants when evaluated for *in vitro* surface properties or for function *in vivo.*

## Surfactant Metabolism and Secretion

The synthesis and secretion of surfactant by the type II cell is a complex sequence that results in the release by exocytosis of lamellar bodies to the alveolus.[22] Enzymes within the endoplasmic reticulum (ER) use glucose, phosphate, and fatty acids as substrates for phospholipid synthesis. The details of how the surfactant lipids condense with SP-B and SP-C to form the surfactant lipoprotein complex within lamellar bodies remain obscure. Ultrastructural abnormalities of type II cells with SP-B deficiency and ABCA3 deficiency in full-term infants indicate that these gene products are essential for lamellar body formation.[23] A basal rate of surfactant secretion occurs continuously, and surfactant secretion can be stimulated by β-agonists and purines, or with lung distention and hyperventilation.

The alveolar pool size of surfactant is about 4 mg/kg in the adult human.[24] The lung tissue of the adult human contains much more surfactant, and only about 7% of the surfactant lipids are in the secreted pool. The surfactant pool size per kilogram probably changes little with age after the newborn period. While no estimates exist for the full-term human, full-term animals have alveolar pool sizes of about 100 mg/kg, and this large pool decreases to adult values by about 1 week of age.[25] The alveolar surfactant pool size in the adult (and presumably young child) is small relative to other mammalian species (e.g., about 30 mg/kg in adult sheep), which may make the human lung more susceptible to surfactant deficiency with lung injury. Infants with respiratory distress syndrome (RDS) have alveolar surfactant pool sizes of less than 5 mg/kg.

The kinetics of surfactant metabolism have been extensively studied in adult, term, and preterm animal models.[26] In all species studied to date, including primates, the surfactant component synthesis to secretion interval is relatively long, and the alveolar half-life of newly secreted surfactant is very long, on the order of 6 days in healthy newborn lambs.[27] The surfactant components are recycled back into type II cells, and recycling is more efficient in newborn than adult animals.[28] These observations have been validated by quite extensive studies in preterm and term humans using stable isotopes to label surfactant precursors or components.[29] A limitation of the studies is the need to have an endotracheal tube in place to allow repetitive sampling of lung fluid. Depending on the labeled precursor, the time from synthesis to peak secretion of new surfactant ranged from 2 to 3 days, and the half-life for clearance was 2 to 4 days in preterm infants. Similar values were measured for term infants. In general, preterm or term infants with lung disease have surfactant with smaller pool sizes, less synthesis and secretion, and shorter half-life values. These measurements include term infants with pneumonia, meconium aspiration syndrome, and congenital diaphragmatic hernia. There are no measurements of surfactant metabolism for older children. In one report in normal adults using sputum samples, peak labeling of surfactant phosphatidylcholine occurred about 2 days after the labeled precursor was given, and the subsequent half-life was about 7 days.[30] These studies demonstrate that the replacement of endogenous surfactant pools is slow, and alveolar pools turn over slowly.

## Alveolar Life Cycle of Surfactant

After secretion, surfactant goes through a series of form transitions in the airspace (Fig. 5.2).[22] The lamellar bodies unravel to form the elegant structure called tubular myelin. This lipoprotein array has SP-A at the corners of the lattice and requires at least SP-A, SP-B, and the phospholipids for its unique structure.[31] Tubular myelin and other large surfactant lipoprotein structures are the reservoir in the fluid hypophase for the formation of the surface film within the alveolus and small airways. The hypophase is a very thin fluid layer covering the distal epithelium with a volume of about 0.5 mL/kg body weight that has a surfactant concentration of approximately 10 mg/mL. New surfactant enters the surface film, and “used” surfactant leaves in the form of small vesicles. The surface-active tubular myelin contains SP-A, SP-B, and SP-C, while the biophysically inactive small vesicles that are recycled and catabolized contain very little surfactant protein. The total surfactant pool size is less than the amount of active surfactant because 30% to 50% of the alveolar phospholipids are in catabolic forms in the normal lung. Pulmonary edema and products of lung injury can accelerate form conversion and cause a depletion of the surface-active fraction of surfactant despite normal or high total surfactant pool sizes.[32] Surfactant is catabolized primarily by type II cells and alveolar macrophages. Granulocyte-macrophage colony-stimulating factor deficiency prevents alveolar macrophages from catabolizing surfactant and results in the clinical syndrome of alveolar proteinosis.[33] The important concept is that the alveolar pool of functional surfactant is maintained by dynamic metabolic processes that include secretion, reuptake, and resecretion balanced by catabolism.

In the alveolar fluid lining layer, the surfactant transforms into tubular myelin and other surfactant protein-rich forms, which facilitate surface adsorption. The lipids are catabolized as small vesicular forms by macrophages and type II cells, and are recycled by type II cells. *SP-A,* Surfactant protein A; *SP-B,* surfactant protein B; *SP-C,* surfactant protein C.

# Surfactant Function

## Alveolar Stability

Alveoli are polygonal with flat surfaces and curvatures where the walls of adjacent alveoli intersect. Alveoli are interdependent in that their structure is determined by the shape and elasticity of neighboring alveolar walls. The forces acting on the pulmonary microstructure are chest wall elasticity, lung tissue elasticity, and surface tensions of the air-fluid interfaces of the small airways and alveoli. Although the surface tension of surfactant decreases with surface area compression and increases with surface area expansion, the surface area of an alveolus changes little with tidal breathing. The low surface tensions resulting from surfactant help to prevent alveolar collapse and keep interstitial fluid from flooding the alveoli. Surfactant also keeps small airways from filling with fluid and thus prevents the potentially ensuing luminal obstruction.[34] If alveoli collapse or fill with fluid, the shape of adjacent alveoli will change, which can result in distortion, overdistention, or collapse. When positive pressure is applied to a surfactant-deficient lung, the more normal alveoli will tend to overexpand, and the alveoli with inadequate surfactant will collapse, generating a nonhomogeneous inflated lung.

## Pressure-Volume Curves

The static effects of surfactant on a surfactant-deficient lung are evident from the pressure-volume curve of the preterm lung (Fig. 5.3). Preterm surfactant-deficient rabbit lungs do not begin to inflate until pressures exceed 20 cm $H_2O$.[35] The pressure needed to open a lung unit is related to the radius of curvature and surface tension of the meniscus of fluid in the airspace leading to the lung unit. The units with larger radii and lower surface tensions will “pop” open first because, with partial expansion, the radius increases and the forces needed to finish opening the unit decrease. Surfactant decreases the opening pressure from greater than 20 to 15 cm $H_2O$ in this example with preterm rabbit lungs. Because surfactant does not alter airway diameter, the decreased opening pressure results from surface adsorption of the surfactant to the fluid in the airways. The inflation is more uniform as more units open at lower pressures, resulting in less over-distention of the open units.

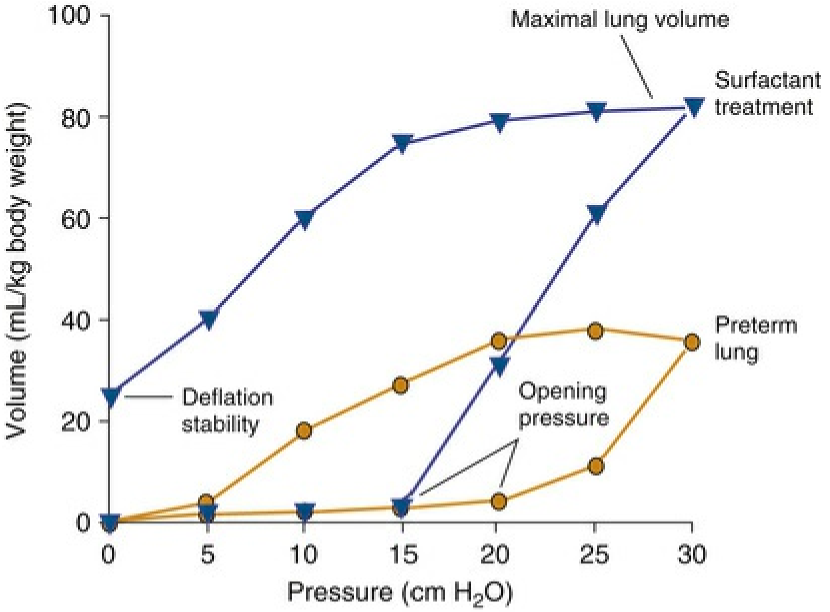

**FIG. 5.3** Effect of surfactant treatment on surfactant-deficient lungs. These idealized pressure-volume curves illustrate the effect of surfactant treatment with natural sheep surfactant on the opening pressure, the maximal lung volume, and the deflation stability of lungs from preterm rabbits. (Curves based on data from Rider ED, Jobe AH, Ikegami M, Sun B. Different ventilation strategies alter surfactant responses in preterm rabbits. *J Appl Physiol.* 1992;73:2089-2096.)

A particularly important effect of surfactant on the surfactant-deficient lung is the increase in maximal volume at maximal pressure. In this example, maximal volume at 30 cm $H_2O$ is increased over two times with surfactant treatment. Surfactant also stabilizes the lung on deflation. The surfactant-deficient lung collapses at low transpulmonary pressures, whereas the surfactant-treated lung retains about 30% of the lung volume on deflation. This retained volume is similar to the total volume of the surfactant-deficient lung at 30 cm $H_2O$ and demonstrates how surfactant treatments increase the functional residual capacity (FRC) of the lung.

## Host Defense Functions of Surfactant

SP-A and SP-D are pattern recognition molecules that bind a variety of polysaccharides, phospholipids, and glycolipids on the surface of bacterial, viral, and fungal pathogens.[6,7] SP-A and SP-D binding forms protein bridges between microbes that induce microbial aggregation and stimulate the recognition, uptake, and clearance of pathogens by host defense cells.[36,37] In addition, SP-A and SP-D binding may have direct antibacterial and antifungal activity by increasing pathogen membrane permeability.[38,39]

Although binding and aggregation of infectious microbes is a critical feature of SP-A and SP-D physiology, these proteins also have more complex roles in host defense.[2] SP-A and SP-D have been implicated in the stimulation and inhibition of several immune pathways. Both SP-A and SP-D bind CD14 and inhibit lipopolysaccharide-induced expression of proinflammatory cytokines through CD14 and toll-like receptor 4.[40–42] SP-A binds toll-like receptor 2 and inhibits proinflammatory cytokine release in response to peptidoglycan.[43] Gardai and colleagues proposed a model by which SP-A and SP-D might stimulate or inhibit inflammation through the competing actions of signal regulating protein $\alpha$ (SIRP$\alpha$) and calreticulin/CD91.[44] Their model suggests that in the unbound state, the CRDs of SP-A or SP-D inhibit macrophage activation by binding to SIRP$\alpha$, which inhibits activation of nuclear factor κB (NFκB). In contrast, if the CRDs of SP-A or SP-D are occupied by a microbial ligand, binding to SIRP$\alpha$ is inhibited and instead the collectins bind to the macrophage activating receptor, calreticulin/CD91, which turns on NFκB and subsequently induces proinflammatory mediator release and alveolar macrophage activation. SP-A also may contribute to adaptive immune responses. SP-A inhibits the maturation of dendritic cells in response to potent T cell stimulators and enhances the endocytic ability of dendritic cells.[45] In addition, SP-A downregulates lymphocyte activity and proliferation.[46]

The hydrophobic surfactant proteins SP-B and SP-C may also have host defense functions. Although SP-B can inhibit bacterial growth *in vitro,* overexpression of SP-B or reduced expression of SP-B in the lungs of mice did not alter bacterial clearance, suggesting that SP-B is not involved in innate host defense.[47] However, elevated levels of SP-B in the lungs of endotoxin-exposed mice decreased pulmonary inflammation.[48] Thus, SP-B may contribute to the modulation of inflammation in the injured lung. SP-C binds lipopolysaccharide and blocks the production of tumor necrosis factor-$\alpha$ by macrophages.[49] However, possible roles for SP-C in bacterial clearance or lung inflammation *in vivo* have not been evaluated.

# Surfactant Deficiency

## The Preterm Infant With Respiratory Distress Syndrome

RDS in preterm infants is a primary surfactant deficiency that initially does not include lung injury, unless antenatal infection complicates the lung disease.[50] The surfactant system normally is mature by about 35 weeks' gestation, but the early appearance of surfactant and lung maturation is frequent in infants delivered prematurely. Early maturation is thought to occur in response to fetal stress resulting in increased fetal cortisol levels, or by exposure of the fetal lung to inflammation as a result of chorioamnionitis.[38] Maternal treatments with corticosteroids are routinely given to decrease the risk of RDS if preterm delivery before 32 to 34 weeks' gestation is anticipated.[51] Induced lung maturation includes not only an induction of surfactant but also thinning of the mesenchyme, which increases lung gas volumes. Unless preterm infants have early lung maturation, they develop progressive respiratory distress from birth, which is characterized by tachypnea, grunting, increased work of breathing, and cyanosis. Infants who have died of RDS have alveolar pool sizes of surfactant of less than 5 mg/kg. Although this amount is similar to the amount of surfactant recovered from healthy adult humans, surfactant from the preterm infant has decreased function, probably because it contains less of the surfactant proteins, which are critical for biophysical function.[52] The surfactant from the preterm infant also is more susceptible to inactivation by edema fluid, and the preterm lung is easily injured if a stable FRC is not maintained or if the lung is overstretched.

## The Injured Mature Lung

Acute respiratory distress syndrome (ARDS) describes an overwhelming inflammatory reaction within the pulmonary parenchyma leading to global lung dysfunction.[53] ARDS is defined by acute onset, an oxygenation index less than 200, bilateral infiltrates on chest x-ray, and a pulmonary capillary wedge pressure of less than 18 mm Hg, or the absence of clinical evidence for left-sided heart failure. The etiology of ARDS is multifactorial and can occur in association with lung injury secondary to trauma, sepsis, aspiration, pneumonia, massive blood transfusions, or near drowning to name some associations. It is a common disease, affecting approximately 15% to 20% of all patients ventilated in the adult intensive care unit (ICU) and 1% to 4.5% of patients in the pediatric ICU. ARDS has a high mortality rate of 40% to 50%.

Impairment of surfactant with ARDS can result from inhibition, degradation, or decreased production.[32,54–56] The proteinaceous pulmonary edema characteristic of ARDS can inactivate surfactant by dilution and by competition for the interface.[54] Plasma proteins known to inhibit surfactant function include serum albumin, globulin, fibrinogen, and C-reactive protein. In addition to proteins, phospholipases, along with their products, fatty acids, and lipids inhibit surface activity. Epithelial cell injury by inflammatory mediators can decrease surfactant production and contribute to surfactant deficiency. Normally in the lung, about 50% of surfactant is present in the bioactive form that has a high SP-B and SP-C content. In ARDS, small vesicular forms increase, and the pool of active surfactant is depleted.

The phospholipid content is decreased and the phospholipid composition is abnormal in bronchoalveolar lavage fluid (BALF) from patients with ARDS.[57] SP-A, SP-B, and SP-C also are decreased in BALF from patients with ARDS. The surfactant protein levels can remain low for at least 14 days after the onset of ARDS. Changes in surfactant composition, including phospholipids, fatty acids, and proteins, likely represent alveolar type II cell injury with altered metabolism, secretion, or recycling of components. SP-A and SP-B concentrations are also reduced in the lungs of patients at risk for ARDS, even before the onset of clinical lung injury. In contrast, SP-D levels in BALF remain normal, except in a subgroup of patients who later died. Decreased SP-D levels in BALF were 85.7% sensitive and 74% specific in predicting death from ARDS.[58]

## Genetic Deficiencies of Surfactant in Mice and Humans

Mice with targeted deletion of the *Sftpa* gene (*Sftpa*$^{-/-}$) for SP-A protein survived normally without changes in surfactant composition, function, secretion, and reuptake; however, there was no tubular myelin.[59] Although seemingly normal at baseline, significant defects were detected in pulmonary host defense in SP-A-deficient mice when they were subjected to a microbial challenge. The clearance of group B *Streptococcus, Haemophilus influenzae,* respiratory syncytial virus (RSV), and *Pseudomonas aeruginosa* was delayed in *Sftpa*$^{-/-}$ mice, and the recognition and uptake of bacteria by alveolar macrophages were deficient.[60–62] Oxygen radical production and killing of engulfed microorganisms by *Sftpa*$^{-/-}$ macrophages were markedly reduced, while markers of lung inflammation were increased following infection in *Sftpa*$^{-/-}$ mice.[63]

Despite the considerable innate immune defects that are associated with SP-A deficiency in animal models, we have yet to find a human susceptibility to pulmonary infection that is caused by a *Sftpa* mutation. However, polymorphisms in the human genes for SP-A affecting their function have been identified, and humans with these polymorphisms have increased susceptibility to acquiring infections with RSV and *Mycobacterium tuberculosis.*[64] Analyses suggest that SP-A polymorphisms may also affect infection severity since patients that are homozygous or heterozygous for asparagine at amino acid position 9 are more likely to need intensive care, mechanical ventilation, or longer hospitalization.[55] Although there are no clear associations between *Sftpa* mutation and pulmonary infection, an association has been reported between a rare heterozygous mutation in the *Sftpa* and adult onset interstitial pulmonary fibrosis and lung cancer.[65] It is likely that these mutations cause SP-A misfolding and the trapping of SP-A in the ER, which leads to chronic ER stress and cell injury.[65]

Mice with deletion of the *Sftpd* gene (*Sftpd*$^{-/-}$) for SP-D protein survived normally, but unlike SP-A-deficient mice that had relatively normal lungs at baseline, *Sftpd*$^{-/-}$ mice spontaneously developed pulmonary inflammation and airspace enlargement. In addition, *Sftpd*$^{-/-}$ mice accumulated increased numbers of apoptotic macrophages, and enlarged, foamy macrophages that released reactive oxygen species and metalloproteinases.[66,67] When *Sftpd*$^{-/-}$ mice were exposed to a microbial challenge, the uptake and clearance of viral pathogens including influenza A and RSV were deficient, whereas the clearance of group B *Streptococcus* and *H. influenzae* were unchanged.[68,69] However, oxygen radical release and production of the proinflammatory mediators were increased in *Sftpd*$^{-/-}$ mice when exposed to either viral or bacterial pathogens indicating that SP-D plays an antiinflammatory role in the lung that is independent of the clearance of pathogens.[63,68,69] SP-D deficiency has not been described in humans, but polymorphisms at amino acid position 11 are associated with increased risk of RSV infection.[70]

Gene-targeted mice lacking SP-B, and infants with hereditary SP-B deficiency, demonstrate the critical role of SP-B in surfactant function, homeostasis, and lung function.[71] Targeted disruption of the mouse SP-B gene causes respiratory failure at birth. Despite normal lung structure, the SP-B-deficient mice failed to inflate their lungs postnatally. Type II cells of SP-B-deficient mice had large multivesicular bodies but did not have lamellar bodies, and the proteolytic processing of pro-SP-C (the preprocessed form of SP-C) was disrupted.[6] Infants with SP-B deficiency die from respiratory distress in the early neonatal period with the same anatomic findings.[72] Mutations leading to partial SP-B function have been associated with chronic lung disease in infants. Because SP-B is required for both intracellular and extracellular aspects of surfactant homeostasis, SP-B deficiency has not been treated successfully with surfactant replacement therapy, and survival is dependent on lung transplantation. It is important to note that mice and infants without the adenosine triphosphate-binding cassette transporter A3 (ABCA3) have type II cells without lamellar bodies and the same lethal respiratory failure phenotype as observed in SP-B deficiency.[73]

SP-C-deficient mice survive and have normal surfactant composition and amounts. However, surfactant isolated from the SP-C-deficient mice forms less stable bubbles, demonstrating a role for SP-C in developing and maintaining lipid films.[74] SP-C mutations were recently identified in patients with familial and sporadic interstitial lung disease.[75] *Sftpc* mutations in these patients alter the ability of the protein to fold correctly and result in the retention of SP-C in the ER and the subsequent development of ER stress which, in turn, leads to pulmonary cell injury and death. Histological features of lung disease in these individuals include lungs with a thickened interstitium, infiltration with inflammatory cells and macrophages, fibrosis, and abnormalities of the respiratory epithelium. In isolated reports, infants with respiratory failure from SP-D deficiency have been supported by tracheostomy and chronic mechanical ventilation for years prior to eventual decannulation and survival off ventilator support.[76]

# Surfactant Treatment of Surfactant Deficiency

## Respiratory Distress Syndrome

The respiratory morbidities of preterm infants with RDS have strikingly decreased in recent years because of the combined effects of antenatal corticosteroid treatments and more gentle approaches to mechanical ventilation.[77] The original randomized trials of surfactant for RDS evaluated treatments given after the disease was established, generally after 6 hours of age.[78] Other trials evaluated treatment of all high-risk infants soon after birth to prevent RDS. Subsequent trials demonstrated that treatments of the highest-risk infants (generally infants with birth weights less than 1 kg) as soon after birth as convenient and before significant mechanical ventilation will minimize lung injury. However, many very low birth weight infants can be transitioned to air breathing successfully using continuous positive airway pressure (CPAP), and the decision to treat with surfactant can be made after the initial stabilization at birth.[79,80] One advantage of allowing the infant to breathe spontaneously with CPAP used to recruit and maintain FRC, is that hyperventilation and overdistention of the delicate preterm lung by mechanical ventilation can be avoided. Larger infants who develop RDS generally are treated with oxygen and nasal CPAP until the oxygen concentration approaches 40%. Then they are treated with surfactant. Preterm infants will respond to surfactant treatments even if the treatment is delayed for several days.

Full-term infants with severe meconium aspiration or pneumonia also will respond to surfactant treatments with improved oxygenation,[81] and surfactant also can improve lung function in infants with the group B streptococcal sepsis/pneumonia syndrome.[82] Current practice is to treat most infants with severe respiratory failure with surfactant because there are no contraindications.

The surfactants that are commercially available for clinical use in infants are made from organic solvent extracts of animal lungs or alveolar lavages of animal lungs. While there are differences in composition, the clinical results do not demonstrate any compelling differences in clinical responses. All of the commercial surfactants lack SP-A and SP-D, contain SP-C, and have variable amounts of SP-B. Surfactants that contain synthetic peptides or surfactant proteins are being developed for clinical use. Surfactants that contain steroids also are being tested as an approach to decreasing bronchopulmonary dysplasia in infants treated for RDS.[83]

## Acute Respiratory Distress Syndrome

ARDS is a significant therapeutic challenge for intensivists despite recent advances in understanding pathophysiology and new treatment modalities. Surfactant content and composition are altered in ARDS, resulting in decreased surface activity, atelectasis, and decreased lung compliance.[54] The injury is generally not uniform throughout the lung, resulting in overinflation of the more normal lung, and atelectasis and filling of alveolar fluid in other lung regions. The injured lung makes less surfactant, and that surfactant is inhibited by the highly proteinaceous edema and inflammatory fluid, and the fluid-filled alveoli are difficult to recruit to improve ventilation. Multiple animal models of ARDS respond very positively to surfactant treatments when combined with lung recruitment ventilation strategies. Unfortunately, multiple, large, randomized, controlled trials using different surfactants have not shown any benefit for surfactant treatments.[84,85] The experience in adult patients with ARDS differs strikingly from the clinical responses of preterm infants with RDS. Somewhere in between are the clinical responses of term infants with meconium aspiration and pneumonia, who have modest, but consistent clinical improvements that can decrease extracorporeal membrane oxygenation (ECMO) use and save lives.[86] Several small trials and clinical experiences suggested that older infants and children with diseases such as acute RSV pneumonia respond to surfactant treatment. A small trial by Wilson and colleagues demonstrated that for a range of children from 1 to 21 years of age with various causes of ventilator dependent ARDS, surfactant treatments improved oxygenation and decreased mortality.[87] However, a subsequent trial of surfactant for children with lung injury/ARDS was stopped for futility after the enrollment of 110 patients.[88] Although surfactant use decreased hospital days, there was no effect on oxygenation or mortality. A recent meta-analysis of three small trials of surfactant for bronchiolitis in infants showed some benefit, but larger trials will be needed to verify this indication.[89] Future studies could explore the potential for surfactant components for host defense in diseases such as ARDS.

# The Structural and Physiologic Basis of Respiratory Disease

*Matthias Ochs MD, Hugh O'Brodovich MD*

Knowledge of the normal development, structure, and physiologic function of the lungs is required to understand the pathophysiology that is seen in disease. Historically, the understanding of lung function was derived solely from clinical observation and postmortem histologic examination. The development of invasive and noninvasive techniques that were capable of assessing lung structure and function in living subjects greatly improved our understanding of lung physiology on an "organ basis." There has been an explosion of knowledge in cellular and molecular biology, which is covered in detail in other chapters. This chapter will focus on the normal structure of the lung and organ physiology.

## Normal Lung Anatomy and Cell Function

Knowledge of normal lung anatomy is one of the basic requirements for understanding lung function in health and disease. Because detailed descriptions of lung anatomy are available elsewhere,[1–3] this section will focus on selected aspects of gross and microscopic anatomy to enable the reader to understand the physiologic changes that occur in congenital and acquired lung disease.

The shape of the lung reveals three faces: the convex costal face opposed to the rib cage, the concave diaphragmatic face resting on the diaphragmatic dome, and the mediastinal face, where the right and left lung are oriented toward each other. The right and left lung are each embedded in a separate pleural cavity and are separated by the mediastinum. Except at the hilum (where airways, vessels, and nerves enter or leave the lung), the lung's outer surface is covered by the visceral pleura, which also extends into the fissures, thereby demarcating the pulmonary lobes (Fig. 6.1).

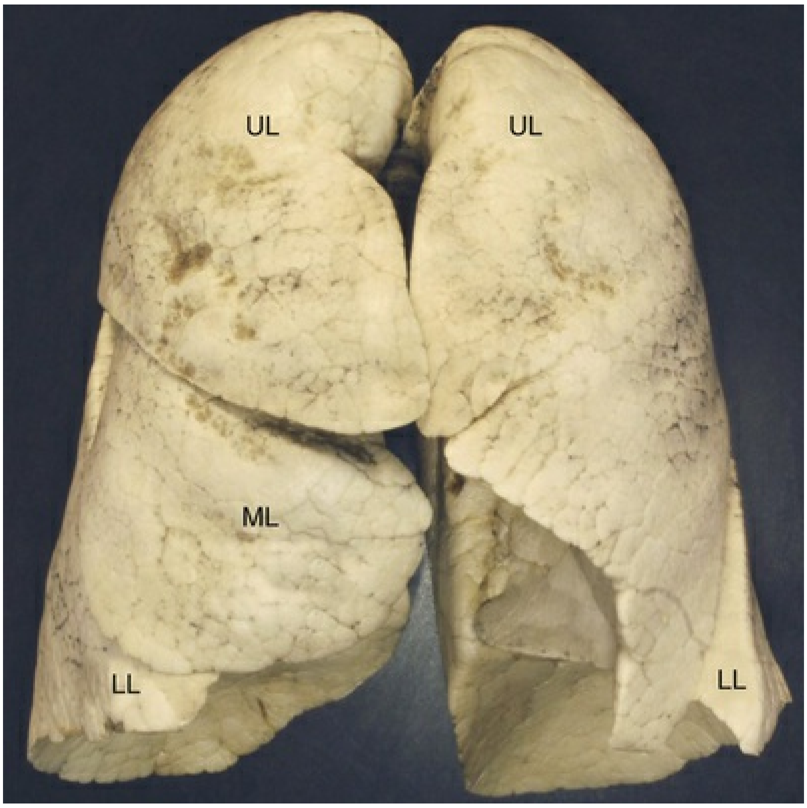

**FIG. 6.1** Dried human lung. The costal and diaphragmatic faces can be seen. The visceral pleura that covers the surface of the lungs extends into the fissures. The oblique fissure separates the upper lobe (UL) and lower lobe (LL) on both sides. The horizontal fissure separates the UL and middle lobe (ML) of the right lung.

# Airways

The airways are composed of two functional compartments. A proximal conducting zone (the bronchial tree) continuously connects to a distal respiratory zone (the alveolar region), where gas exchange takes place. The basic structure of the airways is already present at birth; therefore, neonates and adults share a common bronchopulmonary anatomy (Figs. 6.2 and 6.3). When airways divide, they do so by dichotomous branching, over an average of 23 generations, although the number of times that branching occurs varies. This airway variability has physiologic implications; different pathways will have different resistances to air flow, and a heterogeneous distribution of gases or inhaled particles may occur. As the bronchi branch and decrease in size, they lose their cartilage and become bronchioles. Ultimately, a terminal bronchiole opens into the alveoli-containing gas-exchanging area of the lung. In the human, the gas-exchanging area begins with several generations of respiratory bronchioles (i.e., bronchioles with alveoli attached to their wall) that connect to alveolar ducts whose "wall" completely consists of alveolar openings. The most distal alveolar ducts end in blind alveolar sacs. The unit of lung parenchyma distal to a terminal bronchiole (i.e., the unit in which all airways participate in gas exchange) is termed the *acinus* (Fig. 6.4).[4]

**FIG. 6.4** Model of airway branching in the human lung over an average of 23 generations. The first 14 generations are purely conducting. Transitional airways lead into acinar airways, which contain alveoli and thus participate in gas exchange. (Modified from Weibel ER. *Morphometry of the Human Lung*. Heidelberg: Springer; 1963. From Ochs M,

Weibel ER. Functional design of the human lung for gas exchange. In: Fishman AP, Elias JA, Fishman JA, et al., eds. *Fishman's Pulmonary Diseases and Disorders,* 4th ed. New York: McGraw-Hill; 2008:23-69.)

The airways are lined with a continuous epithelium that gradually changes from a ciliated pseudostratified columnar epithelium in the bronchi to a ciliated simple cuboidal epithelium in smaller bronchioles near the gas-exchanging units. At the transition into the alveolar region, the epithelium abruptly becomes squamous. At all levels, the epithelium is not made of a single cell type, but rather a mosaic of several cell types: lining cells and secretory cells, often with rarer cells with specialized functions interspersed (Fig. 6.5). Ciliated cells predominate throughout the bronchial and bronchiolar epithelium and are responsible for propelling mucus from the peripheral airways to the pharynx (Fig. 6.6). This mucociliary transport system is an important defense mechanism of the lungs. The mucous layer has two parts, a superficial gel layer with high viscosity and a deeper periciliary layer with a brushlike structure.[5] The cilia form a dense, long carpet on top of the epithelial cells, and their coordinated to-and-fro action propels the gel mucous layer toward the oropharynx. Cilia are a derivative of the centrioles, and there are approximately 200 of them on the apex of each ciliated cell. The cilia are anchored within the cell with a basal body that is oriented in the direction of mucous movement. The shaft of the cilium has a central pair of single tubules that are connected via radial spokes to nine peripheral pairs of tubules. The tip of the cilium has tiny hooklets that probably help grab the gel component of the mucous layer and propel it forward. The cilium has a beat frequency of 12 to 20 Hz and is coordinated both with other cilia on that cell and concurrently with the cilia on adjacent cells to yield a synchronized wave flowing up the airway.[6,7] Primary ciliary dyskinesia (PCD) is a group of disorders that includes Kartagener syndrome and the erroneously named *immotile cilia syndrome.* In PCD, there are defects within the tubules, in their inner or outer dynein arms, or in the radial arms that result in a disorganized movement of the cilia that precludes normal mucociliary transport and results in chronic bronchitis and repeated pneumonias (see Chapter 71). Submucosal glands, which are present in large and small bronchi, are the chief source of airway secretions and contain both serous and mucus cells. Goblet cells are seen in the trachea and bronchi (see Fig. 6.6). They produce mucin, a viscous mixture of acid glycoproteins that contributes to the mucous layer. Submucosal glands and goblet cells can increase in number in disorders such as chronic bronchitis, the result being mucous hypersecretion and increased sputum production. The basal cell, commonly seen within the pseudostratified columnar bronchial epithelium resting on the basement membrane but not reaching the lumen, is undifferentiated and acts as a precursor of ciliated or secretory cells (see Fig. 6.6).[8]

**FIG. 6.5** Schematic representation of wall structure along the airways. The epithelium is reduced from pseudostratified to cuboidal and then to squamous, but it retains its mosaic of lining and secretory cells. Only the trachea and bronchi contain cartilage and submucosal glands. Smooth muscle cells disappear in the alveoli. (From Ochs M, Weibel ER. Functional design of the human lung for gas exchange. In: Fishman AP, Elias JA, Fishman JA, et al., eds. *Fishman's Pulmonary Diseases and Disorders,* 4th ed. New York: McGraw-Hill; 2008:23-69.)

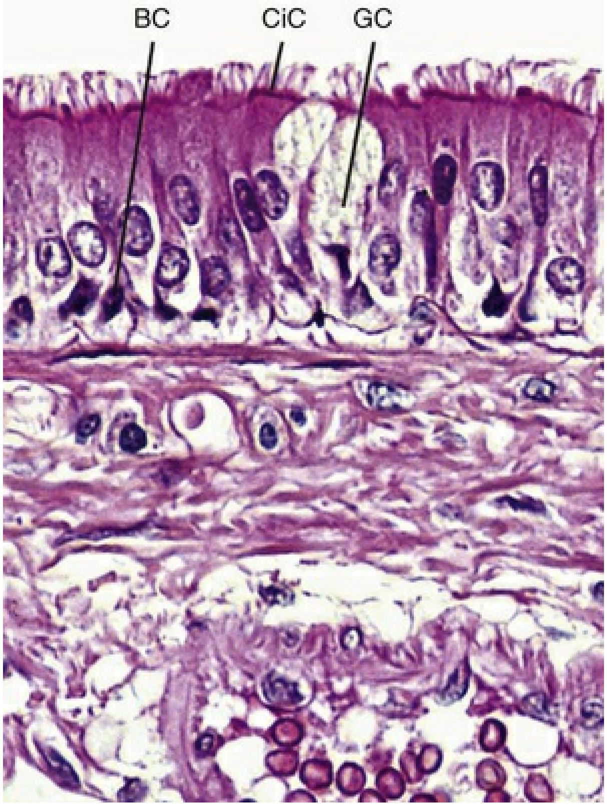

**FIG. 6.6** Light micrograph of the bronchial wall. The major cells types of the pseudostratified columnar respiratory epithelium can be seen: ciliated cells (CiC), goblet cells (GC), and basal cells (BC). The mucosa's connective tissue layer (lamina propria), which contains blood vessels, can be seen underneath the epithelium. (Courtesy of G. Bargsten, Hannover.)

Whereas ciliated cells are still present in smaller bronchioles, goblet cells are gradually replaced by nonciliated bronchiolar epithelial cells (often termed club cells).[9] These cells are characterized by their dome-shaped apex that protrudes into the airway lumen and by secretory granules. Their secretory products, which include the club cell secretory protein (CCSP), add to the bronchiolar lining layer. CCSP is thought to have immunomodulatory functions. In addition, club cells are a site of cytochrome P-450–dependent detoxification of xenobiotics, and they act as progenitor cells for the maintenance of the bronchiolar epithelium.[10]

There are several rarer cell types found within the airways; however, their functional significance is less well understood. The brush cell, which is only rarely found in the human lung, has a dense tuft of broad, short microvilli. It is supposed to "taste" the chemical composition of the airway lining fluid.[11,12] Neuroendocrine cells secrete mediators into subepithelial capillaries. Sometimes these cells are organized in clusters (neuroepithelial bodies) that are thought to have oxygen-sensing functions. Neuroepithelial bodies[13] are found more frequently within the fetal airways or in pediatric disorders characterized by chronic hypoxemia (e.g., bronchopulmonary dysplasia).

Histologically, the remainder of the airway consists of the submucosa, with its network of blood vessels and nerves, and a variable amount of smooth muscle and cartilage. Within the submucosa are mast cells containing vasoactive peptides and amines, cells of the immune system (plasma cells, lymphocytes, and phagocytes), and submucosal glands. In the main stem bronchi, cartilage is present in C-shaped rings. However, as further branching of bronchi occurs, progressively less cartilage is present as plates. Cartilage adds structural rigidity to the airway and thus plays an important role in maintaining airway patency, especially during expiration. Congenital deficiency of airway cartilage and hence airway instability has been associated with bronchiectasis (Williams-Campbell syndrome) and congenital lobar hyperinflation (previously referred to as *congenital lobar emphysema*).

The smooth muscle content of the airway also varies with its anatomic location. In the largest airways, a muscle bundle connects the two ends of the C-shaped cartilage. As the amount of cartilage decreases, the smooth muscle assumes a helical orientation and gradually becomes thinner, ultimately reaching the alveolar ducts where the smooth muscle cells lie in the alveolar entrance rings. Muscle contraction increases airway rigidity in all airways.

Although it has been widely assumed that the airway muscles of newborn infants are inadequate for bronchoconstriction, this assumption is not correct. Even premature infants have smooth muscle, and although the amount may be statistically less than that seen in adults, it is likely enough to constrict the infant's much more compliant airways. Indeed, pulmonary function test results have demonstrated that airway resistance can be altered with bronchodilating drugs. The belief that infants have little or no smooth muscle in their airways is even less tenable in such disorders as Northway's old bronchopulmonary dysplasia[14] and left-to-right congenital heart disease, in which hypertrophy of the airway smooth muscle has been demonstrated by morphometric measurement. Congenital deficiency of large-airway smooth muscle and elastic fibers is associated with marked dilation of the trachea and bronchi, which promotes retention of airway secretions and ultimately leads to recurrent pulmonary sepsis, a condition known as the Mounier-Kuhn syndrome or tracheobronchomegaly.

## Alveolar Region

Within the pulmonary lobule, defined as the smallest unit of lung structure marginated by connective tissue septae, one finds the lungs' region for gas exchange. The terminal respiratory (gas-exchanging) unit consists of the structures distal to the terminal bronchiole: the respiratory bronchioles (bronchioles with alveoli budding from their walls), alveolar ducts, and alveoli (Fig. 6.7).

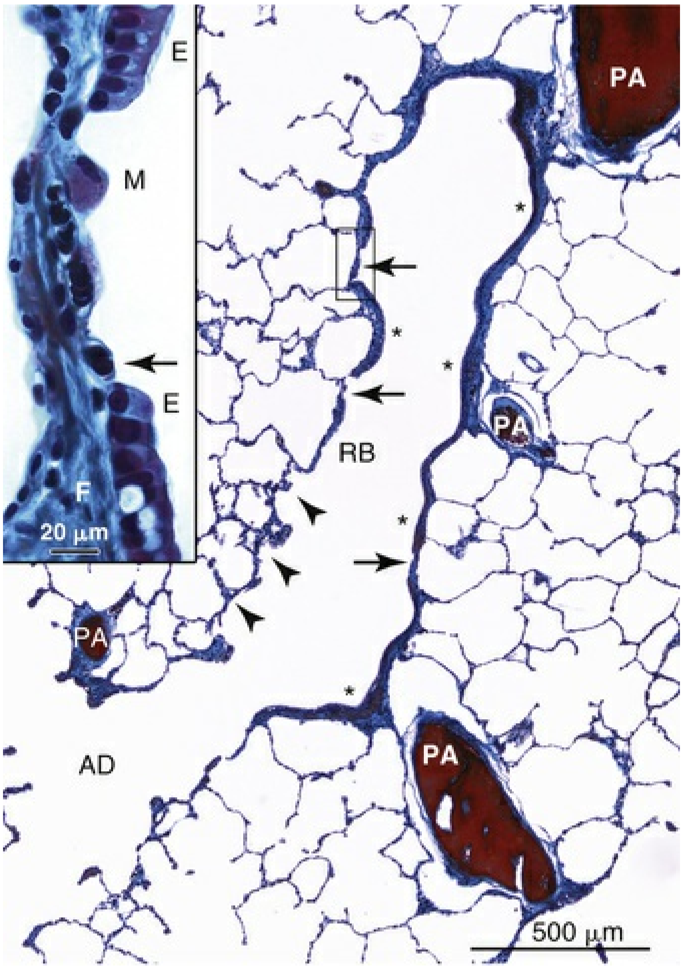

**FIG. 6.7** Light micrograph of respiratory bronchiole (RB) from human lung seen extending into alveolar ducts (AD). The wall is lined by typical bronchiolar cuboidal epithelium *(asterisks),* which is interrupted by respiratory patches *(arrows)* and alveoli proper *(arrowheads).* Note pulmonary artery branches (PA) following the respiratory bronchiole. *Inset:* Respiratory patch with capillary *(arrow)* and macrophage (M). The cuboidal ciliated epithelium (E) is replaced by thin squamous type I alveolar epithelial cells. Note thick fibrous layer (F) with smooth muscle cells. (From Ochs M, Weibel ER. Functional design of the human lung for gas exchange. In: Fishman AP, Elias JA, Fishman JA, et al., eds. *Fishman's Pulmonary Diseases and Disorders*, 4th ed. New York: McGraw-Hill; 2008: 23-69.)

As mentioned earlier in the chapter, the acinus is the portion of lung parenchyma distal to a terminal bronchiole (see Fig. 6.4). It is the basic functional gas-exchanging unit of the lung. The acinus is approximately 6 to 10 mm in diameter in the adult lung. In the adult lung, these units have a total gas volume of 2000 to 4000 mL and a surface area of about 140 $m^2$ (Table 6.1),[15] yet all alveoli are within 5 mm of the closest terminal bronchiole. True alveoli are not spherical but more closely resemble hexagons with flat, sheetlike surfaces. The average alveolar diameter ranges from 200 to 300 μm. Within the acini, interalveolar holes (termed *pores of Kohn*) are present in alveolar walls. Although they have been thought to provide channels for collateral ventilation, the fact that pores of Kohn are covered with surfactant[16] needs to be taken into consideration. Ultrastructural evidence suggests that they are used by alveolar macrophages to reach neighboring alveoli. In the newborn lung, there are few, if any, pores of Kohn. This might contribute to the fact that relative to adult lung, infant lung is more predisposed to patchy atelectasis.

### Table 6.1

**The Human Lung in Numbers**

| | |
|---|---|
| Alveolar number | 480 million |
| Alveolar surface area | 140 $m^2$ |
| Capillary volume | 210 mL |
| Air-blood barrier thickness | 2 μm |

Data from Gehr P, Bachofen M, Weibel ER. The normal lung: ultrastructure and morphometric estimation of diffusion capacity. *Resp Physiol.* 1978;32:121-140; Ochs M, Nyengaard JR, Jung A, et al. The number of alveoli in the human lung. *Am J Respir Crit Care Med.* 2004;169:120-124.

The alveoli are lined by two types of epithelial cells (Fig. 6.8). Type I alveolar epithelial cells are extremely broad, thin (0.1 to 0.5 μm) cells that in total cover about 95% of the alveolar surface. They are markedly differentiated cells that possess few organelles, and because their cytoplasmic leaflets are so thin, they provide an epithelial barrier for gas exchange that cannot be resolved by routine histology.[17] Recent work has demonstrated that these cells are capable of actively transporting $Na^+$ with $Cl^-$ and water following, and thus participate in the clearance of airspace fluid (see Chapter 36).[18] Type II epithelial cells are more numerous than type I cells, but because of their cuboidal shape, they occupy only about 5% of the total alveolar surface area (Table 6.2). They are characterized histologically by microvilli and osmophilic inclusions termed *lamellar bodies,* which are storage sites for surfactant components (see Fig. 6.8).[19,20]

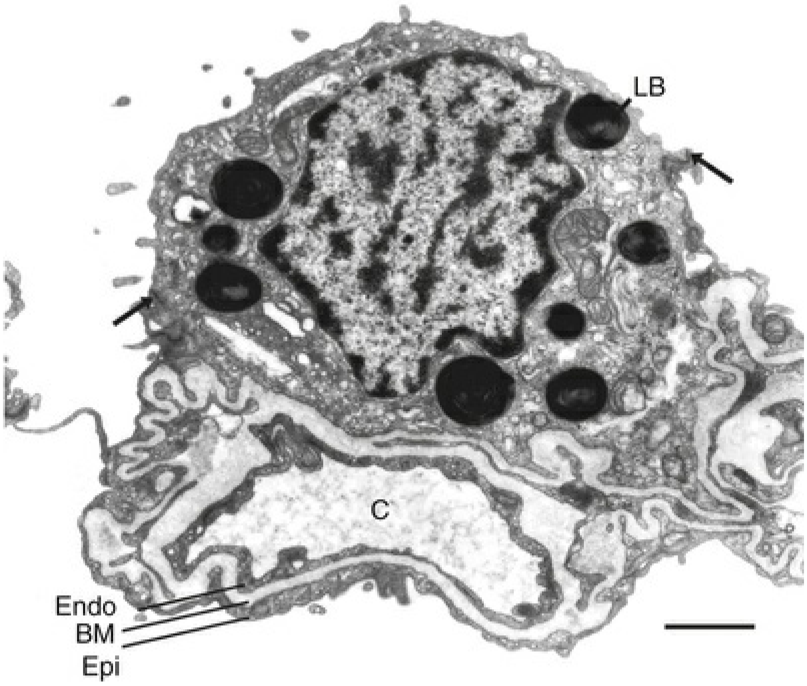

**FIG. 6.8** Electron micrograph of a human type II alveolar epithelial cell. The phospholipid-rich surfactant material is stored in lamellar bodies (LB) prior to secretion. On both sides, thin cell extensions of type I alveolar epithelial cells form tight junctions with the type II cell *(arrows).* A capillary (C) is seen underneath the type II cell. The thin side of the air-blood barrier is trilaminar and consists of the alveolar epithelium (Epi), fused basement membranes (BM) and the capillary endothelium (Endo). Scale bar = 1 μm. (From Ochs M. A brief update on lung stereology. *J Microsc.* 2006;222:188-200.)

## Table 6.2

## Cellular Characteristics of the Human Lung

| Cell Type | Total Cells (%) | Cell Volume (μm$^3$) | Apical Surface Area (μm$^2$) |
|---|---|---|---|
| Epithelium | 8 | 1764 | 5098 |
| Alveolar type I | 16 | 889 | 183 |
| Alveolar type II | | | |
| Endothelium | 30 | 632 | 1353 |
| Interstitial | 36 | 637 | |
| Alveolar macrophages | 10 | 2492 | |

Data from Crapo JD, Barry BE, Gehr P, et al. Cell number and cell characteristics of the normal human lung. *Am Rev Respir Dis.* 1982;125:332-337.

The type II alveolar epithelial cell maintains homeostasis within the alveolar space in several ways. First, it is the source of pulmonary surfactant and as such is one index of fetal lung maturity; surfactant decreases the surface tension at the alveolar air-liquid interface. Second, in the postnatal lung, this cell is the precursor of the type I alveolar epithelial cell and thus plays a key role in the normal maintenance of the alveolar epithelium as well as in the repair process following lung injury when progenitor cells from type II alveolar epithelium contribute to alveolar renewal, repair and cancer.[21,22] Third, it is capable of actively transporting ions against an electrochemical gradient and is involved in both fetal lung liquid secretion, in airspace fluid reabsorption at birth, and in the postnatal reabsorption of fluid from the airspace following the development of alveolar pulmonary edema (see the discussion on fetal lung liquid secretion in "The Lung at Birth" later in this chapter). Two pediatric disorders associated with the type II alveolar epithelial cell are (1) its lack of maturity and surfactant secretion in respiratory distress syndrome (RDS) of preterm infants and (2) its decreased lamellar body formation and surfactant secretion in surfactant dysfunction mutations (e.g., in genes encoding surfactant protein B or the lipid transporter ABCA3).

The cell junctions (zonulae occludentes) between type I and type II alveolar epithelial cells are very tight and thus restrict the movement of both macromolecules and small ions (e.g., sodium and chloride) (see Fig. 6.8). This tightness is an essential characteristic of the cells lining the alveolar space; it enables the active transport of ions. Also, these tight junctions provide a margin of safety for patients who are susceptible to pulmonary edema; significant interstitial pulmonary edema can be present without alveolar flooding, thus preserving gas exchange.

There is a thick side and a thin side to the alveolar air-blood barrier. Gas exchange is thought to occur predominantly on the thin side where there are only the thin extensions of type I alveolar epithelial cells, fused basement membranes, and capillary endothelial cells (see Fig. 6.8). Capillaries undergo considerable stress (e.g., during exercise or lung hyperinflation) and must have great tensile strength. This strength is mainly imparted by type IV collagen located in the basement membrane. The thick side of the barrier consists of connective tissue, amorphous ground substance, and scattered fibroblasts. The thick side, in addition to providing structural support, acts as a site of fluid and solute exchange.[23]

# Pulmonary Vascular System

The lung receives blood from both ventricles. In the postnatal lung, the entire right ventricular output enters the lung via the pulmonary arteries, and blood ultimately reaches the gas-exchanging units by one of the pulmonary arterial branching systems. Arterial branches accompany the bronchial tree and divide with it, each branch accompanying the appropriate bronchial division (see Fig. 6.3B). In addition, supernumerary arteries take off at right angles and directly supply the gas-exchanging units (see Fig. 6.3C). The pulmonary capillary bed is the largest vascular bed in the body and covers a surface area of about 120 to 130 $m^2$. The network of capillaries is so dense that it may be thought of as a sheet of blood interrupted by small vertical supporting posts. The pulmonary veins that lie at the boundaries between lung units defined by bronchoarterial divisions return blood to the left atrium. By virtue of their larger numbers and thinner walls, the pulmonary veins provide a large reservoir for blood and help maintain a constant left ventricular output in the face of a variable pulmonary arterial flow.

The bronchial arteries (usually three originating directly or indirectly from the aorta, but variable in number)[24,25] provide a source of well-oxygenated systemic blood to the lung's tissues.[26,27] This blood supply nourishes the walls of the bronchi and proximal bronchioles, larger blood vessels, and nerves in addition to perfusing the lymph nodes and most of the visceral pleura. There are numerous communications between the bronchial arterial system and the remainder of the pulmonary vascular bed: a portion of the blood returns to the right atrium via bronchial veins, and a portion drains into the left atrium via pulmonary veins. Although the bronchial arteries normally receive only 1% to 2% of the cardiac output, they hypertrophy in chronically infected lungs, and blood flow may easily increase by more than 10-fold. This is clinically important because virtually all hemoptysis originates from the bronchial vessels in disorders such as cystic fibrosis or other causes of suppurative bronchiectasis.

Histologically, the pulmonary arteries can be classified as elastic, muscular, partially muscular, or nonmuscular. The elastic pulmonary arteries are characterized by elastic fibers embedded in their muscular coat, whereas the smaller muscular arteries have a circular layer of smooth muscle cells bounded by internal and external elastic laminae. As arteries decrease further in size, only a spiral of smooth muscle remains (partially muscular arteries), which ultimately disappears so that vessels still larger than capillaries have no muscle in their walls (nonmuscular arteries). In the adult lung, elastic arteries are greater than 1000 μm in diameter, and muscular arteries are usually in the range of 250 μm. In the pediatric age group, histologic structure is not as easily determined from vessel size. During lung growth, a remodeling of the pulmonary vasculature occurs. Muscularization of the arteries lags behind multiplication of alveoli and appearance of new arteries. Therefore, the patient's age must be considered before histologic structure can be assumed from vessel size within the pulmonary acinus (Fig. 6.9). Notably, in the fetus and newborn, the amount of pulmonary arterial smooth muscle is increased. This is functionally important because high pulmonary arterial resistance is a feature of the fetal circulation in association with a large right to left shunt via the ductus arteriosus.

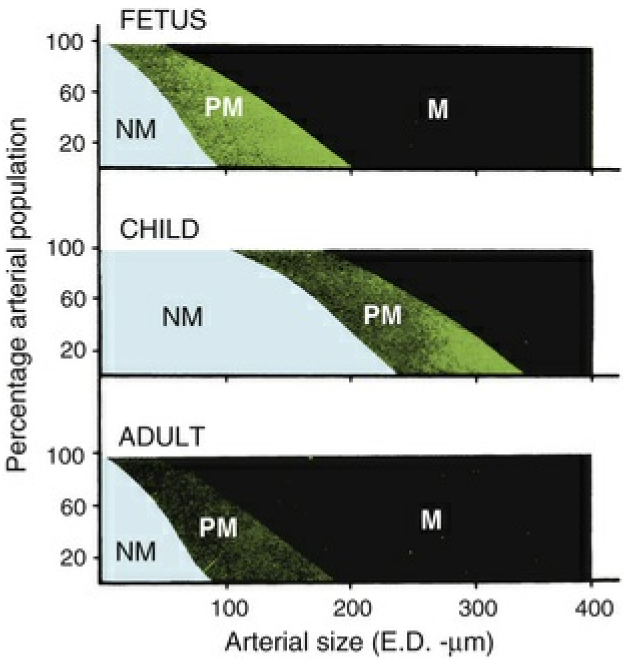

**FIG. 6.9** The populations of the three arterial types: muscular (M), partially muscular (PM), and nonmuscular (NM), in the fetus, child, and adult. The distribution of structure in size is similar in the fetus and the adult, whereas during childhood NM and PM structures are found in much larger arteries. *E.D.*, External diameter. (From Reid LM. The pulmonary circulation. Remodeling in growth and disease. *Am Rev Respir Dis.* 1979;119:531.)

The endothelium of the pulmonary vascular system is continuous and nonfenestrated. It is an intensely active cell layer and is not just serving a passive barrier function. The endothelial cell produces a glycocalyx that interacts with blood-borne substances and blood cellular elements, thereby influencing such homeostatic functions as hemostasis. The endothelium produces von Willebrand factor, which is part of the factor VIII complex and is necessary for normal platelet function. Within endothelial cells, von Willebrand factor is stored in specific granules termed *Weibel-Palade bodies*.[28] Similarly, there are enzymes located on the surface and within the endothelial cell itself that are capable of synthesizing, altering, or degrading blood-borne vasoactive products. The individual cells are separated by gaps of approximately 3.5 nm in radius, which allow the free movement of water and small ions but restrict the movement of proteins. The cells and the basement membrane on which they sit carry different net surface charges, which affect the movement of anionic macromolecules such as proteins and thus affect lung water and solute exchange (see Chapter 36). The capacity of the pulmonary endothelium and its basement membrane to restrict fluid and protein movement is impressive. It has been estimated that in the adult human, the amount of lung lymph flow is only 10 to 20 mL/h despite a total blood flow of 300,000 mL/h.

## Lymphatic System

There is an extensive interconnecting network of lymphatic vessels throughout the lung. The major function of this network is to collect the protein and water that has moved out of the pulmonary vascular space and to return it to the circulation, thus maintaining the lung at an appropriate degree of hydration. The lymphatic vessels travel alongside the blood vessels in the loose connective tissue of the pleura and bronchovascular spaces. It is likely that there are no lymphatics within the alveolar wall itself and that juxta-alveolar lymphatics represent the beginning of the pulmonary lymphatic system. Histologically, the lymphatic capillaries consist of thin, irregular endothelial cells that lack a basement membrane. Occasionally, there are large gaps between endothelial cells that allow direct communication with the interstitial space. Larger lymphatic vessels contain smooth muscle in their walls that undergoes rhythmic contraction. This muscular contraction plus the presence of funnel-shaped, monocuspid valves ensures an efficient unidirectional flow of lymph. In addition to helping maintain lung water balance, the lymphatic system is one of the pulmonary defense mechanisms. It aids in removal of particulate matter from the lung, and aggregates of lymph tissue near major airways contribute to the host's immune response.

## Innervation of the Lung

The lung is innervated by both components of the autonomic nervous system.[29] Parasympathetic nerves arise from the vagus nerve, and sympathetic nerves are derived from the upper thoracic and cervical ganglia of the sympathetic trunk. These branches congregate around the hila of the lung to form the pulmonary plexus. Myelinated and nonmyelinated fibers then enter the lung tissues and travel along with and innervate the airways and blood vessels. Although the anatomic location of pulmonary nerves has been elucidated, their physiologic role in health and disease is incompletely understood. In general, the airways constrict in response to vagal stimulation and dilate in response to adrenergic stimulation. The postnatal pulmonary vasculature appears to be maximally dilated under normal conditions, and it is difficult to demonstrate any significant physiologic effect of either parasympathetic or sympathetic stimulation. The vascular response, however, is influenced by age and initial vascular tone. For example, in fetal lungs where there is an abundance of pulmonary vascular smooth muscle, vagal stimulation results in significant vasodilation, and sympathetic stimulation results in marked vasoconstriction.

Sensory nerves from the lungs are vagal in origin and arise from slowly and rapidly adapting receptors and from C-fiber receptors. The slowly adapting (stretch) receptors, located in the smooth muscle of the airway, are stimulated by an increase in lung volume or transpulmonary pressure. They induce several physiologic responses including inhibition of inspiration (Hering-Breuer reflex), bronchodilation, increased heart rate, and decreased systemic vascular resistance. The rapidly adapting vagal (irritant) receptors are activated by a wide variety of noxious stimuli, ranging from mechanical stimulation of the airways to anaphylactic reactions within the lung parenchyma. The rapidly adapting receptors induce hyperpnea, cough, and constriction of the airways and larynx. C-fiber receptors are the terminus of nonmyelinated vagal afferents. They include the J receptors that are located near the pulmonary capillaries and are stimulated by pulmonary congestion and edema; they evoke a sensation of dyspnea and induce rapid, shallow breathing along with laryngeal constriction during expiration.

In addition to the sympathetic and parasympathetic nervous systems, humans and several other species have a third nervous system within their lungs. The noncommittal name *nonadrenergic noncholinergic nervous system* has been chosen because its function and properties are not understood. Purines, substance P, and vasoactive intestinal polypeptide have been suggested as possible neurotransmitters for this system.

## Interstitium

The interstitium plays several roles in lung function in addition to providing a structural framework that consists of insoluble proteins. The ground substance influences cell growth and differentiation and lung water and solute movement. The cells contained within the interstitial region of the lung not only play individual roles that result from their contractile or synthetic properties, but they also interact with other cells (e.g., the endothelium and epithelium) to alter the basic structure and function of the lung.

A continuous fiber scaffold is present in the interstitium with an axial system (along the airways from the hilum to the alveolar ducts), a peripheral system (along the visceral pleura into interlobular septa), and a septal system (along the alveolar septa) (Fig. 6.10).[30] Most of the interstitial matrix of the lung is composed of type I collagen which, along with the less common collagen subtypes, forms a structural fibrous framework within the lung. Elastin provides elasticity and support to the structures. Both elastin and collagen turn over very slowly under normal conditions. However, rapid remodeling with changes in these proteins sometimes occurs. In diseases such as $\alpha_1$-antitrypsin deficiency (where neutrophil elastases degrade elastin) and pulmonary fibrosis (where there is increased amounts of collagen), there are marked qualitative and quantitative changes in these proteins. The remainder of the matrix is made up of proteoglycans and glycosaminoglycans. These carbohydrate-protein complexes can affect cell proliferation and differentiation in addition to their known effect on cell adhesion and attachment (e.g., laminin) and ability to diminish fluid movement (glycosaminoglycans).

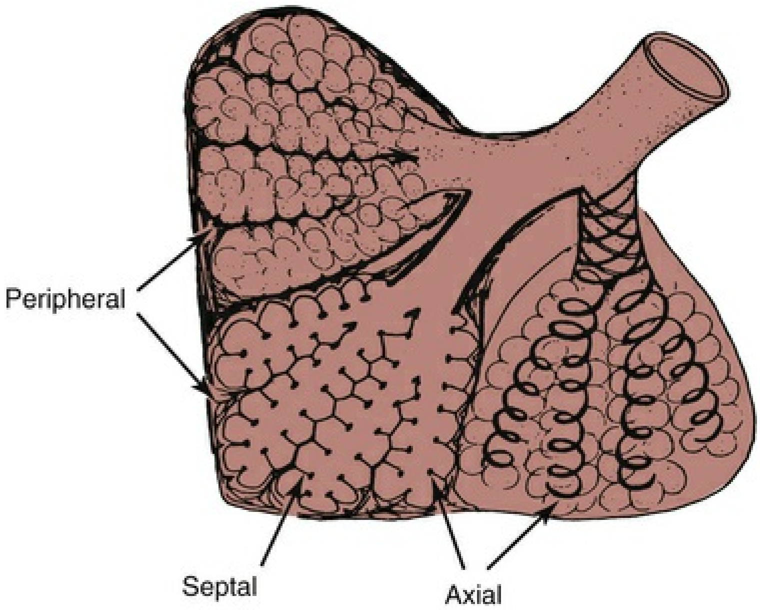

**FIG. 6.10** Schematic diagram of the fibrous support of the lung. (See text for detail.) (From Weibel ER, Bachofen H. How to stabilize the alveoli. Surfactant or fibers. *News Physiol Sci.* 1987;2:72-75.)

Fibroblasts are capable of synthesizing components of the extracellular matrix (e.g., collagen, elastin, and glycosaminoglycans) and hence contribute significantly to the composition of the lung's interstitial space. They can be found within all of the interstitial regions of the lung, although their apparent structure may change, emphasizing the heterogeneity of this cell population.[31] For example, there are fibroblasts with contractile properties (myofibroblasts), some of which also contain lipid bodies in their cytoplasm (lipofibroblasts), although lipofibroblasts are not a common cell type in the human lung.[32] Similarly, it is likely that morphologically similar fibroblasts are not similar in terms of proliferative capacity and ability to synthesize various types of collagen. Data suggest that fibrotic lung diseases are characterized by the loss of the normal heterogeneous fibroblast population and that there may be a selection for certain clones that promote inappropriate focal collagen deposition within the lung parenchyma.

Smooth muscle cells influence the bronchomotor and vasomotor tone within the conducting airways and blood vessels. They are also seen within the free edge of the alveolar septa together with elastic fibers where they form an alveolar entrance ring that is capable of constricting or dilating. The smooth muscle cells form bundles connected by nexus or gap junctions that enable electrical coupling and synchronous contraction. The pericyte is another contractile interstitial cell that is found embedded in the endothelial basement membrane. It is believed to be a precursor cell that can differentiate into other cell types such as mature vascular smooth muscle cells.

There are a variety of interstitial cells that are concerned with innate and adaptive defense of the lung.[33,34] The interstitial macrophage and the alveolar macrophage are major effectors of the innate immune system, which they manage by ingesting particulate matter and removing it from the lung or by processing proteins or other antigens for presentation to adaptive immune cells. These macrophages are capable of secreting many compounds, including proteases and cytokines (substances capable of modulating the growth and function of other cells). B and T lymphocytes, including subsets such as T-regulatory cells (T-reg), are present in the lung and especially within the bronchus-associated lymphoid tissue (BALT), where they contribute to the humoral and cellular-mediated immune response. Further details on the innate and adaptive immune system are available in Chapter 8.

Although not within the interstitium per se, there are large numbers of intravascular cells such as granulocytes that adhere to the pulmonary endothelium. Indeed, next to the bone marrow and spleen, there are more granulocytes within the lung than in any other organ. These granulocytes can be released into the systemic circulation during such stimuli as exercise or the infusion of adrenalin, and this demargination is responsible for the concomitant blood leukocytosis. These leukocytes are also in a prime location for movement into the lung should an infection or inflammatory stimulus occur. There is much evidence to suggest that the pulmonary granulocyte contributes to the pulmonary dysfunction seen in acute lung injury or acute RDS. Leukocytes also contain proteases that are thought to play a role in the development of emphysema and in the lung destruction that occurs in cystic fibrosis.

## Growth and Development of the Lung

## Prenatal Lung Growth

Lung development has been divided into various stages with names that reflect the respective histological appearance of the lung, the region of the lung that is most obviously developing, or both. The literature quotes different ranges for the different stages of human lung development. This concept is reinforced by the "overlap" between the different stages indicated in Fig. 6.11. However, the available data contrasts with the mouse where at least the airway branching pattern is remarkably stereotypical in that all fetuses develop along the same timeline.[35] It may be that there are inadequate data for the human fetal lung to detect this stereotypical development during the longer gestation or that, as with all developmental profiles, each individual human fetus develops along its own timeline. Prenatal lung growth and development is discussed in greater detail in the literature[36–38] and in Chapter 2.

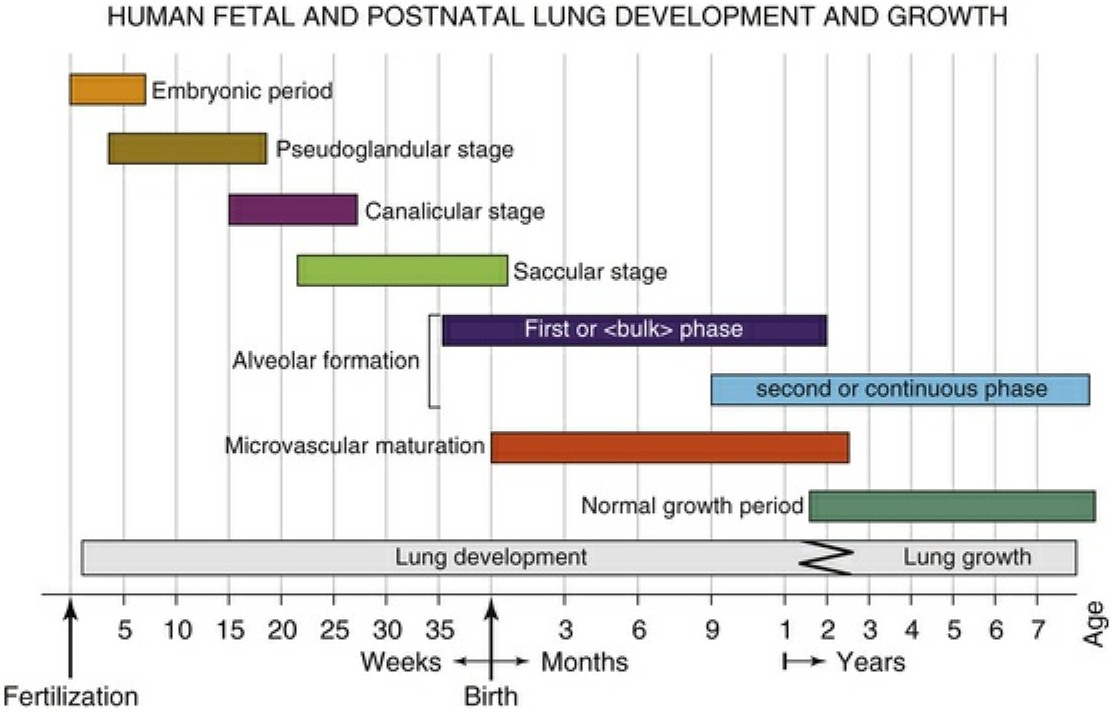

**FIG. 6.11** Various stages of lung development. The actual separation of individual stages is not discrete, and it overlaps. (Modified by M. Ochs, Peter Burri and Ewald Weibel from Zeltner TB, Burri PH. The postnatal development and growth of the human lung. II. Morphology. *Respir Physiol.* 1987;67:269-282.)

The embryonic stage is the first stage of human fetal lung development and takes place from approximately 3 to 6 weeks' gestational age (GA). The lung first appears as a ventral outpouching of the primitive gut. The primary bronchi elongate into the mesenchyme and divide into the two main bronchi. Another key event is that the main pulmonary artery arises from the sixth pharyngeal arch. Congenital abnormalities of the lung may occur during this stage (e.g., lung agenesis, tracheobronchial fistula).

The pseudoglandular stage occurs from approximately 6 to 16 weeks' GA. During this period, airway branching continues and the mesenchyme differentiates into cartilage, smooth muscle, and connective tissue around the epithelial tubes. By the end of the pseudoglandular period, all major conducting airways, including the terminal bronchioles, have formed. Arteries are evident alongside the conducting airways, and by the end of the pseudoglandular period, all preacinar arterial branches have formed. Congenital abnormalities of the lung may occur during this stage (e.g., bronchopulmonary sequestration, cystic adenomatoid malformation, and congenital diaphragmatic hernia).

The canalicular stage occurs from approximately 16 to 26 weeks' GA, and during that time, the respiratory bronchioles develop. By the end of this stage, each ends in a *terminal sac* (also termed a *saccule*). The glandular appearance is lost as the interstitium has less connective tissue and the lung develops a rich vascular supply that is closely associated with the respiratory bronchioles.

The saccular stage occurs from approximately 26 to 36 weeks' GA. During this period, significant capillary proliferation and thinning of the epithelium permits close contact between the airspace and the bloodstream, thus enabling gas exchange. Elastic fibers, which will be important in subsequent true alveolar development, begin to be laid down. At this time, cuboidal (type II) and thin (type I) epithelial cells begin to line the airspace.

The alveolar period commences at approximately 36 weeks' GA. Secondary septa form on the walls of the saccules and grow into the lumen forming the walls of true alveoli.

Distention of the lungs' airspaces by fetal lung liquid is essential for normal lung development. This fluid is neither a mere ultrafiltrate of plasma nor aspirated amniotic fluid. Rather it is generated by the epithelium's active secretion of chloride into the developing lung's lumen with sodium and water following passively (Fig. 6.12A). An inadequate amount of fetal lung liquid is associated with lung hypoplasia.

**FIG. 6.12** (A) The polarized epithelium lining the fetal lung's lumen actively secretes $Cl^-$, with $Na^+$ and $H_2O$ following, which creates in the fluid that distends the fetal lung. $Cl^-$ enters on the basolateral side through membrane-bound protein transporters and is secreted out the apical membrane through different chloride channels, one of which is the chloride channel encoded by the cystic fibrosis transmembrane regulator (CFTR). The electrochemical gradient that drives the secretion is created by the basolateral $Na^+/K^+$ ATPase and $K^+$ permeant ion channels. (B) The polarized epithelium lining the perinatal and postnatal distal lung actively absorbs $Na^+$, with $Cl^-$ and $H_2O$ following, which clears the fetal lung liquid that is present at birth. $Na^+$ enters the cell down its electrochemical gradient through membrane-bound Na permeant ion channels located on the apical membrane. The basolateral $Na^+/K^+$ ATPase extrudes the intracellular $Na^+$ across the basolateral membrane to the interstitial space. The electrochemical gradient that drives the absorption is created by the basolateral $Na^+/K^+$ ATPase and $K^+$ permeant ion channels. A recent summary of research on luminal lung liquid and electrolyte transport is available. (From Hughes JMB, Pride NB. Examination of the carbon monoxide diffusing capacity (DLCO) in relation to its KCO and components. *Am J Respir Crit Care Med*. 2012;186:132-139.)

Congenital abnormalities of the lung may occur during the various stages.[38] In addition, factors such as oligohydramnios or decreased fetal breathing may interfere with the development of the distal lung unit, including the development of alveoli. In contrast, if there is obstruction to outflow of tracheal fluid, as occurs in laryngeal atresia, there is pulmonary hyperplasia.

# The Lung at Birth

Many dramatic changes must occur in the lungs during the transition from intrauterine to extrauterine life. The lung's epithelium must change from fluid secretion to fluid absorption, the distal lung units must fill with and retain inhaled air, and blood flow must increase approximately 20-fold.

At the time of birth, the lungs contain approximately 30 mL/kg of fetal lung liquid. Approximately ⅓ of this fluid is squeezed out during a vaginal delivery, but all of the fluid remains in the airspaces in an infant born by cesarean section. Thus, fetal lung liquid secretion must either greatly decrease or cease totally, and the fluid must be removed. Catecholamines released during labor can temporarily convert the fetal lung from a fluid-secreting organ to a fluid-absorbing organ[39] by initiating the active transport of sodium by the distal lung epithelium (see Fig. 6.12B). The clearance of fetal lung liquid from the newborn's airspaces takes many hours, and the increase in oxygen tension at the time of birth[40] is one key factor that permanently converts the lung epithelium into a sodium-absorbing mode.

*In utero,* little blood flows through the lung despite a relatively high perfusion pressure. This is because of the abundance of pulmonary vascular smooth muscle and the vasoconstrictor effect of the low fetal partial pressure of oxygen ($PO_2$) (<30 mm Hg).

Although during the last trimester, concomitant with surfactant production, blood flow increases to 7% of the cardiac output, it is only at birth that marked increases in the capacity and distensibility of the pulmonary vasculature occur. Several mechanisms are responsible for the changes in circulation. Inflation of the lung with air results in mechanical distention of the vessels, and improvement in oxygenation removes hypoxic vasoconstriction. In addition, the increase in partial pressure of oxygen in arterial blood ($PaO_2$) and changes in flow result in the release of mediators that contribute to the vasoconstriction of the ductus arteriosus[41] and umbilical vessels and dilation of the pulmonary vascular bed. After birth the vessels dilate, which allows the necessary blood flow to the lungs, and the measured wall/lumen ratio decreases. After about 10 days of extrauterine life, the lumina are wider, regardless of the GA of the baby.

# Postnatal Lung Growth

Postnatal lung growth continues throughout infancy and childhood and into the adolescent years. Throughout life, the average values of lung lobe weight expressed as a percentage of total lung weight are approximately: right upper lobe 20%, right middle lobe 8%, right lower lobe 25%, left upper lobe 22%, and left lower lobe 25%. Throughout the pediatric years, the tracheal diameter approximately triples, and the airways increase in their cross-sectional diameter (Fig. 6.13). Excised human lung studies suggest that this growth occurs until around 5 years of age and is associated with marked changes in the relative conductance of central versus more peripheral airways (Fig. 6.14).

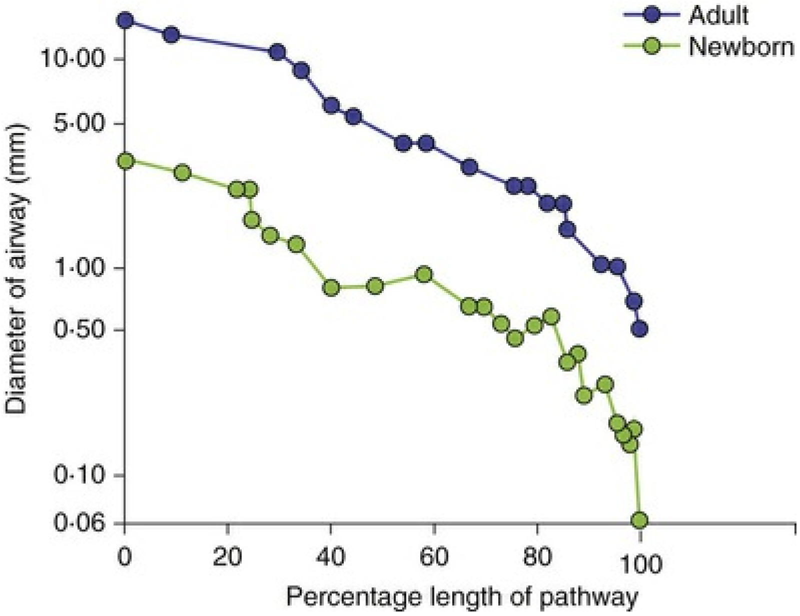

**FIG. 6.13** Diameter of the airway at different percentage points along the axial pathway in an adult lung and in the newborn lung. The pathway begins at the trachea, and the distal end of the terminal bronchiole corresponds to the 100% point. (Reproduced from Hislop A, Muir DC, Jacobsen M, et al. Postnatal growth and function of the pre-acinar airways. *Thorax.* 1972;27:265-274.)

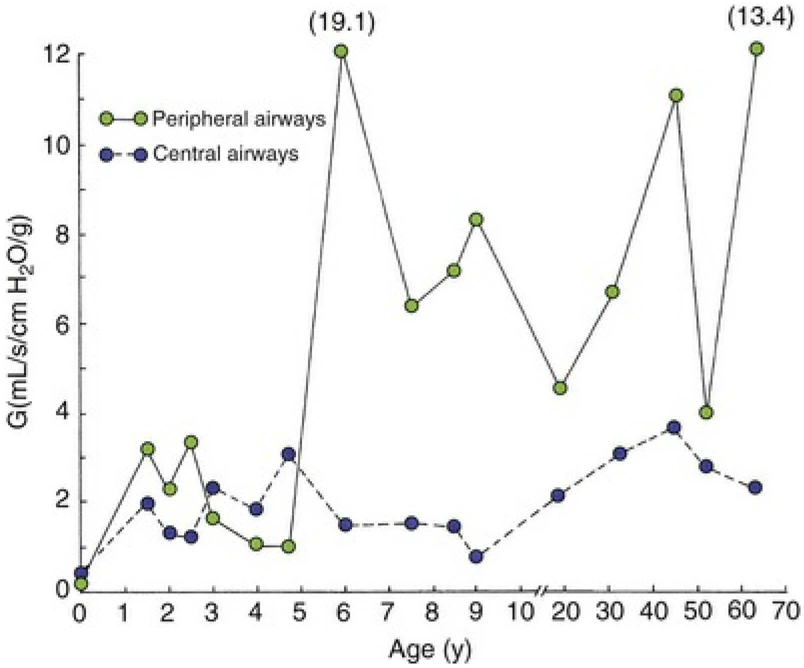

**FIG. 6.14** Comparison of peripheral and central airway conductance as a function of age in normal human lungs. The data are corrected for size by expressing

the conductance as mL/sec/g of lung and for lung inflation by expressing all data at a transpulmonary pressure of 5 cm $H_2O$. (Replotted from Hogg JC, Williams J, Richardson JB, et al. Age as a factor in the distribution of lower-airway conductance and in the pathologic anatomy of obstructive lung disease. *N Engl J Med.* 1970;282:1283.)

Most postnatal lung growth involves the acinar area. New secondary septa continue to appear on the walls of the saccules and grow into the airspace, thus creating more true alveoli. Alveoli continue to increase in number through segmentation of these primitive alveoli and through transformation of terminal bronchioles into respiratory bronchioles, the latter being a process known as *alveolarization.* Alveolar dimensions and number both increase as the lungs and body grow with the internal surface area of the lung paralleling body mass (~1 to 1.5 $m^2$/kg of body weight). It is agreed that alveoli appear prior to birth, and various studies have suggested that there are approximately 20 to 150 million alveoli at birth. A morphometric study[42] of the lungs of 56 infants and children who died suddenly or after a brief illness indicates that there are approximately 200 to 300 million alveoli by the end of the second year of life, at which time alveolar multiplication slows markedly. After 2 years of age, boys have a larger number of alveoli and alveolar surface area than girls regardless of age and stature. Although recent observations[43,44] suggest that alveolarization continues during adolescence, very few new alveoli develop after 8 years of age.[42] Animal and human case studies suggest that the adult lung can, under certain circumstances, develop a small number of new alveoli.[45–47] After alveolar multiplication stops, further growth of the airspace occurs through an increase in alveolar dimensions. In the mature adult lung, the final number of alveoli averages 480 million[48] with individual subjects varying from 200 million to 800 million. The final number is related to total lung volume. An individual alveolus is 200 to 300 μm in diameter. As alveolar multiplication occurs, new blood vessels appear within the acinus. This explains the commensurate increase in the single breath diffusing capacity for carbon monoxide (CO) as the lungs grow.[49]

Prenatal (saccular) walls, as well as secondary septa that form postnatally during the alveolar period, contain a double-capillary network. The adult lung, however, contains a single capillary layer interwoven with a sheet of septal connective tissue. The phase of remodeling the septal capillary bilayer into a single layer (microvascular maturation) occurs from early after birth up to the age of about 2 to 3 years.

Healthy children grow along their lung function growth curve[50,51] similar to how children grow along their own height curve. For example, if a healthy child is born with lung volumes at the 10th percentile, he or she will usually maintain this status throughout childhood. It is known that the reference equations for lung function measurements must be adjusted for African-American children, since they have lower lung function for a given height compared to Caucasian children.[52] Indeed, genetic analyses have shown that the forced expiratory flow in 1 second ($FEV_1$) and forced vital capacity (FVC) are related to the number of ancestral markers related to African ancestry.[53]

When the structure and mechanical behavior of the young infant's and child's respiratory system are compared to those of the mature, but not the elderly, adult, important differences emerge that are likely to influence the pattern of disease. Some of these differences, such as reduced lung recoil, are shared by the infant and elderly and likely influence the pattern of respiratory disease in both populations. The young lung lacks elastic recoil, because elastin is still being created; as a result, airways are less well supported, and there is greater airway closure; this favors inhomogeneity of gas exchange and the development of patchy atelectasis. The elderly have low lung recoil, because they have lost elastin through the aging process, and there is greater loss of recoil when elastin degradation occurs by mechanisms promoting emphysema. The chest wall is relatively more compliant in the young child and stiffens with increasing age. As a result, the infant can develop paradoxical respiration. Respiratory muscle activation during inspiration can produce inward displacement of the rib cage, contributing to increased respiratory work for a given level of ventilation, particularly during rapid eye movement (REM) sleep. The deformability of the chest wall influences findings on physical examination. Chest wall–abdominal paradox may be normal in the premature infant during REM sleep but not in the older child or adult.

Postnatal lung growth can be impaired by restriction of the lung (e.g., in kyphoscoliosis) or augmented (e.g., in remaining lung post pneumonectomy). Lung capacities and airway flows continue to increase until late adolescence. Once adult life is achieved, then nonsmoking men and women have an annual decline in their $FEV_1$ of approximately 20 mL/year.[54] The rate of decline during adult life is increased when individuals smoke or have a history of repeated childhood respiratory disorders.

# Ventilation and Mechanics of Breathing

The principal function of the lung is to perform gas exchange, that is, to enrich the blood with oxygen and cleanse it of carbon dioxide. An essential feature of normal gas exchange is that the volume and distribution of ventilation are appropriate. Ventilation of the lung depends on the adequacy of the respiratory pump (muscles and chest wall) and the mechanical properties of the airways and gas-exchanging units.

It is traditional and useful to consider mechanical events as belonging to two main categories: the static-elastic properties of the lungs and chest wall and the flow-resistive or dynamic aspects of moving air. Changes in one category may be associated with compensatory changes in the other. Thus, many diseases affect both static and dynamic behavior of the lungs. Often, the principal derangement is in the elastic properties of the tissues or in the dimensions of the airways, and the treatment or alleviation of symptoms depends on distinguishing between them.

Before we discuss the mechanical aspects of lung function and gas exchange, it is important to review several basic physical laws concerning the behavior of gases and also the related abbreviations and symbols that will be used.

# Definitions and Symbols

The principal variables for gases are as follows:

V = gas volume
$\dot{V}$ = volume of gas per unit time
P = pressure
F = fractional concentration in dry gas
R = respiratory exchange ratio, carbon dioxide/oxygen
f = frequency
DL = diffusing capacity of lung

The designation of which volume or pressure is cited requires a small capital letter after the principal variable. Thus, $VO_2$ = volume of oxygen; PB = barometric pressure.

I = inspired gas
e = expired gas
a = alveolar gas
t = tidal gas
d = dead space gas
b = barometric pressure

When both location of the gas and its species are to be indicated, the order is $VIO_2$, which means the volume of inspired oxygen.

STPD = standard temperature, pressure, dry (0° C, 760 mm Hg)
btps = body temperature, pressure, saturated with water vapor
atps = ambient temperature, pressure, saturated with water vapor

The principal designations for blood are as follows:

S = percentage saturation of gas in blood
C = concentration of gas per 100 mL of blood
Q = volume of blood
$\dot{Q}$ = blood flow per minute
a = arterial
$\bar{V}$ = mixed venous

c = capillary

All sites of blood determinations are indicated by lowercase initials. Thus, $PaCO_2$ = partial pressure of carbon dioxide in arterial blood; $P\bar{V}O_2$ = partial pressure of oxygen in mixed venous blood; and $PaO_2$ = partial pressure of oxygen in a capillary.

The measurement of pressures can be confusing because pressure can be expressed using different units. For example, atmospheric pressure at sea level can be expressed by many seemingly different, but similar, values: it is important to remember the following:

$$\begin{aligned}1 \text{ atmosphere} = 100 \text{ kilopascals (kPa)} &= 760 \text{ mm Hg}\\ &= 760 \text{ Torr}\end{aligned}$$

The unit Torr is named after Evangelista Torricelli, who discovered the principle of the barometer and used the height of a column of mercury to measure pressures; for general use, one can use the following equation:

$$1 \text{ mm Hg} = 1 \text{ Torr}$$

Both pleural space and ventilator pressures are typically described as cm $H_2O$, since a water-filled manometer was the initial tool used to measure these pressures; it was very hard to measure these low pressures by looking at only millimeter changes in the height of a column of mercury. Care must be taken when reviewing the literature on pulmonary vascular pressures as they can be expressed in either mm Hg or cm $H_2O$. The conversion from cm $H_2O$ to mm Hg is as follows:

$$1 \text{ cm } H_2O = 0.736 \text{ mm Hg}$$

## Properties of Gases

Gases behave as an enormous number of tiny particles in constant motion. Their behavior is governed by the gas laws, which are essential to the understanding of pulmonary physiology.

Dalton's law states that the total pressure exerted by a gas mixture is equal to the sum of the pressures of the individual gases. The pressure exerted by each component is independent of the other gases in the mixture. For instance, at sea level, air saturated with water vapor at a temperature of 37°C has a total pressure equal to the atmospheric or barometric pressure with the partial pressures of the components as follows:

$$\begin{aligned} P\text{B} = 760 \text{ mm Hg} = P\text{H}_2\text{O}(47 \text{ mm Hg}) + \\ P\text{O}_2(149.2 \text{ mm Hg}) + P\text{N}_2(563.5 \text{ mm Hg}) + \\ P\text{CO}_2(0.3 \text{ mm Hg}) \end{aligned}$$

The gas in alveoli contains 5.6% carbon dioxide, BTPS. If $P\text{B} = 760$ mm Hg, then,

$$P\text{ACO}_2 = 0.056(760 - 47) = 40 \text{ mm Hg.}$$

Boyle's law states that at a constant temperature, the volume of any gas varies inversely as the pressure to which the gas is subjected since pressure times volumes is a constant. Because respiratory volume measurements may be made at different barometric pressures, it is important to know the barometric pressure and to convert to standard pressure, which is considered to be 760 mm Hg.

Charles' law states that if the pressure is constant, the volume of a gas increases in direct proportion to the absolute temperature. At absolute zero (−273°C), molecular motion ceases. With increasing temperature, molecular collisions increase so that at constant pressure volume must increase.

In all respiratory calculations, water vapor pressure must be taken into account. The partial pressure of water vapor increases with temperature but is independent of atmospheric pressure. At body temperature (37°C), fully saturated gas has a $P\text{H}_2\text{O}$ of 47 mm Hg.

Gases may exist in physical solution in a liquid, escape from the liquid, or return to it. At equilibrium, the partial pressure of a gas in a liquid medium exposed to a gas phase is equal in the two phases. Note that in blood, the sum of the partial pressures of all the gases does not necessarily equal atmospheric pressure. For example, in venous blood, $P_{O_2}$ has fallen from the 100 mm Hg of the arterial blood to 40 mm Hg, while partial pressure of carbon dioxide ($P_{CO_2}$) has changed from 40 to 46 mm Hg. Thus, the sum of the partial pressures of $O_2$, $CO_2$, and $N_2$ in venous blood equals 655 mm Hg. This provides the physiologic reason why patients who experience a pneumothorax can eventually reabsorb their pneumothorax and do so more rapidly if they inhale gases with an $F_IO_2 > 0.21$.

## Elastic Recoil of the Lung

The lung is an elastic structure that tends to decrease its size at all volumes. The elasticity of the lung depends on the structural components, the geometry of the terminal airspaces, and the presence of an air-liquid interface. When a lung is made airless and is then inflated with liquid, the elastic recoil pressure at large volumes is less than half that of a lung inflated to the same volume with air (Fig. 6.15). Thus, the most significant determinant of the elastic properties of the lung is the presence of an air-liquid interface.

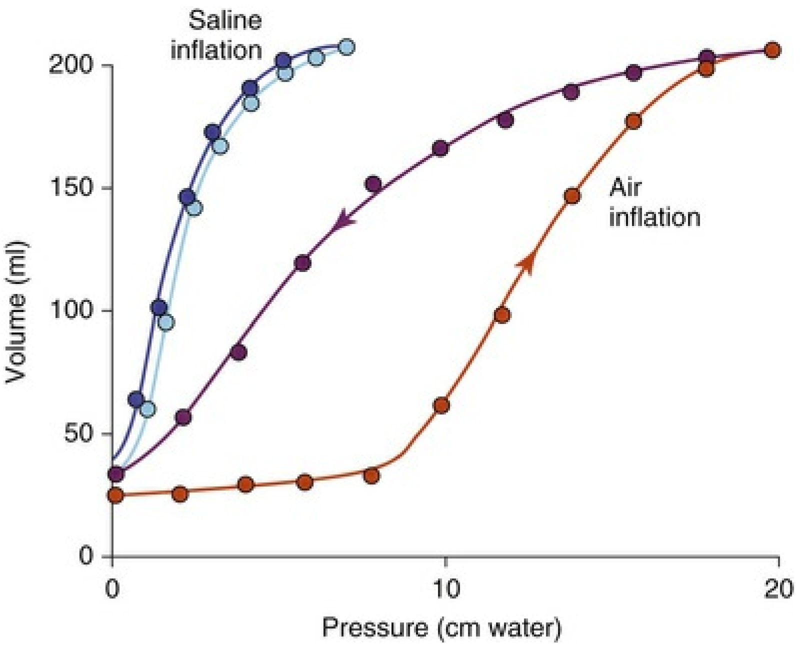

**FIG. 6.15** Comparison of pressure-volume curves of air-filled and saline-filled lungs (cat). *Open circles,* inflation, *closed circles,* deflation. Note that the saline-filled lung has a much higher compliance and also much less hysteresis than the air-filled lung. (From West JB. *Respiratory Physiology—The Essentials*, 8th ed. Baltimore: Williams & Wilkins; 2008.)

The increase of elastic recoil in the presence of an air-liquid interface results from the forces of surface tension. What is surface tension? When molecules are aligned at an air-liquid interface, they lack opposing molecules on one side. The intermolecular attractive forces are then unbalanced, and the resultant force tends to move molecules away from the interface. The effect is to reduce the area of the surface to a minimum. In the lungs, the forces at the air-liquid interface operate to reduce the internal surface area of the lung, and thus they augment elastic recoil. A remarkable property of the material at the alveolar interface, the alveolar lining layer containing pulmonary surfactant, is its ability to achieve a high surface tension at large lung volumes and a low surface tension at low volumes. Surfactant is a phospholipid-protein complex that when compressed forms insoluble, folded-surface films of low surface tension. The ability to achieve a low surface tension at low lung volumes tends to stabilize the airspaces and prevent their closure.

The exact method of lung stabilization and the concomitant role of surfactant in this stabilization can be debated. The classic interpretation is that without surfactant, the smaller alveoli would tend to empty into the larger alveoli in accordance with the Laplace relationship, which relates the pressure across a surface (P) to surface tension (T) and radius (r) of curvature. For a spherical surface, $P = 2T/r$. The smaller the radius, the greater is the tendency to collapse. The difficulty with this hypothesis is that the individual lung units are drawn as independent but communicating bubbles or spheres (Fig. 6.16A). This is not representative of structure of the lung because the alveolar walls are planar and not spherical. In addition, the inside wall of one alveolus is the outside wall of the adjacent alveolus. This last explanation has been utilized to develop the interdependence model of lung stability, which indicates that surface and tissue forces interact to maintain the lungs' inherent structure with the fibrous components playing an important role (see Fig. 6.16B).

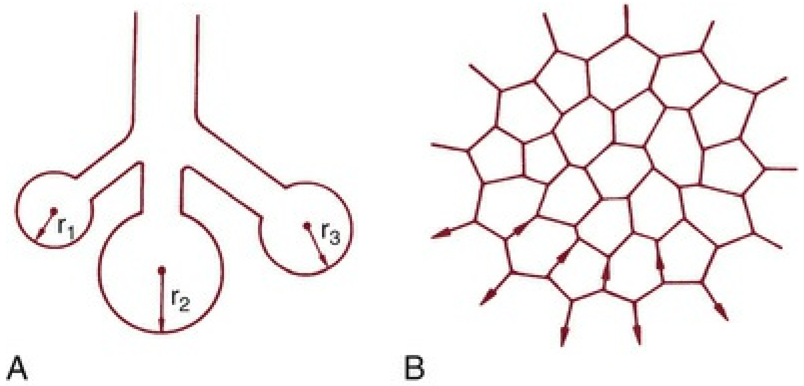

**FIG. 6.16** (A) Classic model of the distal lung, in which individual alveoli would be controlled by Laplace's law: $P = 2\gamma/r$. Small alveoli would empty into large alveoli. (B) Interdependence model of the lung, in which alveoli share common planar and not spherical walls. Any decrease in the size of one alveolus would be stabilized by the adjacent alveoli. (From Weibel ER, Bachofen H. How to stabilize the alveoli. Surfactant or fibers. *News Physiol Sci.* 1987;2:72-75.)

The elastic recoil of the lung is responsible for the lung's tendency to pull away from the chest wall with the resultant subatmospheric pressure in the pleural space. Lung recoil can therefore be derived from measurement of the pleural pressure when no air flow is occurring and alveolar pressure is zero. (The pressure measurement is taken with the patient holding his or her breath for a brief period with the glottis open.)

The pressure within the esophagus can be used as an index for mean pleural pressure. This is a reasonable assumption as long as there is no paradoxical rib cage movement. However, it is not a reasonable assumption for premature infants, term infants in REM sleep, and older infants with severe lung disease. For these infants, no average pleural pressure exists, and calculations of resistance and compliance will not be accurate using this method. When pleural pressure is estimated with an esophageal balloon, one must be careful to avoid artifacts resulting from the gravitational pressure of the mediastinum. For this reason, these measurements are best performed with the patient in the upright or lateral rather than the supine position. Once a series of pressure measurements has been made during brief breath-holds at different lung volumes, a pressure-volume curve of the lung can be constructed (Fig. 6.17).

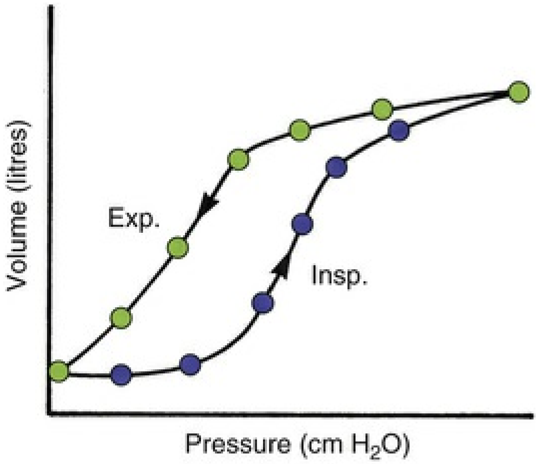

**FIG. 6.17** Pressure-volume curve of a normal lung. Pleural pressure and lung volume are simultaneously determined during brief breath-holds. Lung compliance is calculated from data obtained on the expiratory portion of the pressure-volume curve.

# Compliance of the Lung

The pressure-volume curve of the lung describes two measurements of the elastic properties of the lung: elastic recoil pressure and lung compliance. Elastic recoil pressure is the pressure generated at a given lung volume, whereas compliance is the slope of the pressure-volume curve, or the volume change per unit of pressure:

$$\text{Compliance} = \frac{\Delta\text{volume}}{\Delta\text{pressure}} = \frac{\text{L}}{\text{cm H}_2\text{O}}$$

Compliance depends on the initial lung volume from which the change in volume is measured and the ventilatory events immediately preceding the measurement as well as the properties of the lung itself. At large lung volumes, compliance is lower, because the lung is nearer its elastic limit. If the subject has breathed with a fixed tidal volume (VT) for some minutes, portions of the lung are not participating in ventilation, and compliance may be reduced. A few deep breaths, with return to the initial volume, will increase compliance. Thus, a careful description of associated events is required for correct interpretation of the measurement.

Changes in total lung compliance occur with age for two reasons; the lung's elastic recoil increases during childhood prior to declining during later adult life,[55] and the smaller the subject, the smaller is the change in volume for the same change in pressure. For example, $\Delta V/\Delta P$ is close to 6 mL/cm $H_2O$ in infants, and is 125 to 190 mL/cm $H_2O$ in adults. It is more relevant to a description of the elastic properties of the lung to express the compliance in relation to a unit of lung volume such as the functional residual capacity (FRC). When this is done, the compliance of the lung/FRC, or the specific compliance, changes much less. It is worth reemphasizing that total lung compliance is a function not only of the lung's tissue and surface tension characteristics but also of its volume. This is especially important to remember when compliance has been measured in newborn infants with RDS. The total compliance is a composite of the lung's elastic properties and the number of open lung units. In RDS, sudden changes in total measured compliance (if uncorrected for simultaneously measured lung gas volume) will predominantly, if not exclusively, reflect the opening and closing of individual lung units.

Lung compliance may also be measured during quiet breathing with pressure and volume being recorded at end-inspiration and end-expiration. The resultant value is the dynamic lung compliance. Although dynamic lung compliance does reflect the elastic properties of the normal lung, it is also influenced by the pressure required to move air within the airways. Therefore, dynamic lung compliance increases with increased respiratory rate and with increased airway resistance. Air flow is still occurring within the lung after it has ceased at the mouth, and pleural pressure reflects both the elastic recoil of the lung and the pressure required to overcome the increased airway resistance. Indeed, dynamic lung compliance can be used as a sensitive test of obstructive airway disease.

## Elastic Properties of the Chest Wall

The chest wall is also an elastic structure, but in contrast to the lung, it tends to push outward at low volumes and inward at high volumes. For example, when air is introduced into the pleural space: the lung collapses and the chest wall springs outward.

Compliance of the chest wall can be measured by considering the pressure difference between the pleural space or esophagus and the atmosphere, per change in volume. Significant changes in thoracic compliance occur with age (Fig. 6.18). In the range of normal breathing, the thorax of the infant is nearly infinitely compliant. The pressures measured at different lung volumes are about the same across the lung as those measured across lung and thorax together. The functional significance of the high compliance of the neonatal thorax is observed when there is lung disease. The necessarily greater inspiratory effort and more negative pleural pressure can “suck” in the chest wall, resulting in less effective gas exchange and a higher work of breathing.

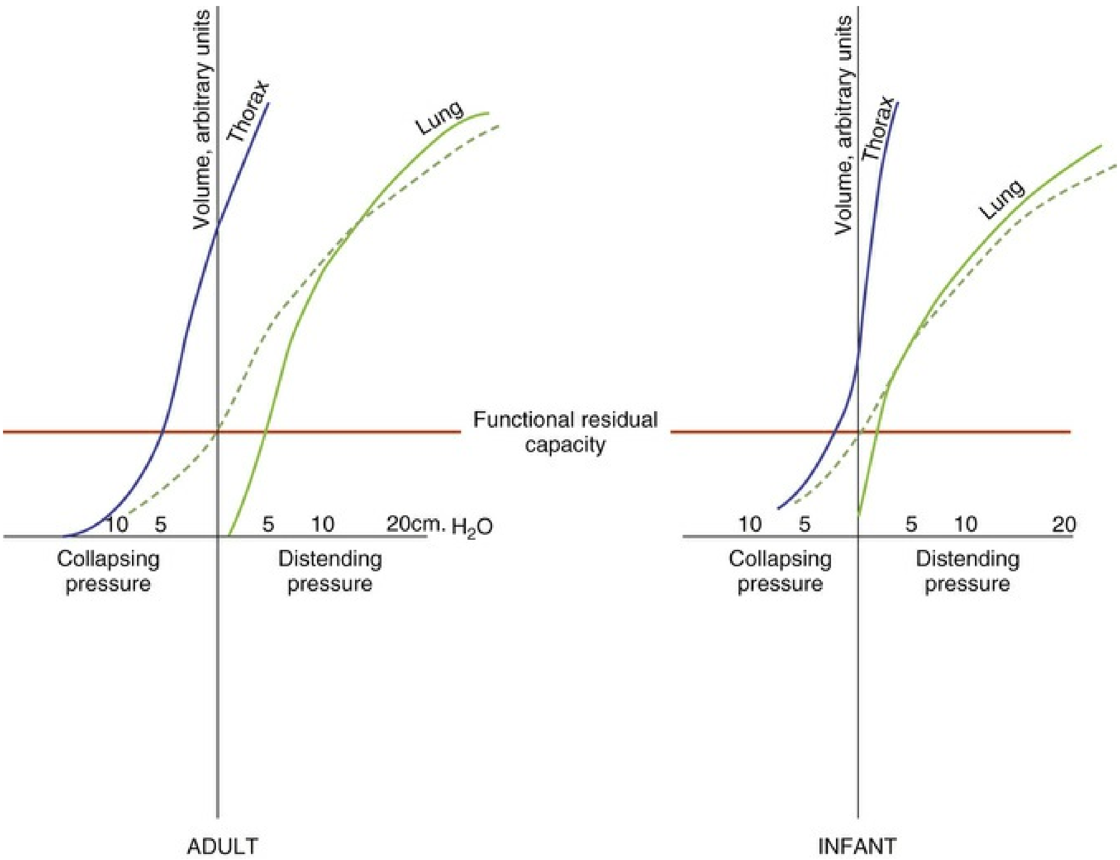

**FIG. 6.18** Pressure-volume relations of lungs and thorax in an adult and in an infant. The *dashed line* represents the characteristic of lungs and thorax together. Transpulmonary pressure at the resting portion (functional residual capacity) is less in the infant, and thoracic compliance is greater in the infant.

With advancing age, the thorax becomes relatively stiffer.[56] Changes in volume-pressure relations are profitably considered only if referred to a reliable unit, such as a unit of lung volume or a percentage of total lung capacity (TLC). Considered on a percentage basis, compliance of the thorax decreases with age. It remains unclear how much of this change is contributed by changes in tissue properties (e.g., increasing calcification of ribs and connective tissue changes) and how much is a disproportionate growth of the chest wall relative to the lung.

# Lung Volumes

## Definition

The partition of commonly used lung volumes can be understood by studying Fig. 6.19. The spirogram on the left represents the volume of air breathed in and out by a normal subject. The first portion of the tracing illustrates normal breathing and is called the tidal volume (VT). The subject then makes a maximal inspiration followed by a maximum expiration: the volume of expired air is the vital capacity (VC). The volume of air that still remains in the lung after a maximal expiration is the residual volume (RV), whereas the volume of air remaining in the lung after a normal passive expiration with relaxed respiratory muscles is the FRC. The maximum amount of air that a subject can have in the lungs is called the TLC. In healthy young subjects, TLC correlates best with the subject's sitting height.

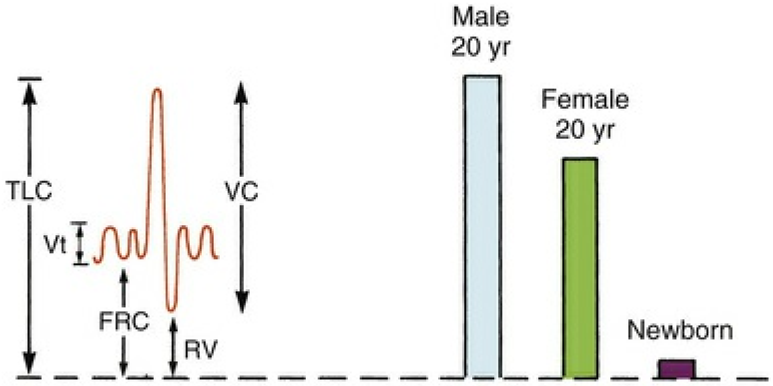

**FIG. 6.19** The lung volumes. The spirogram *(left)* demonstrates normal breathing followed by a maximal inspiratory effort and a maximal expiratory effort. *FRC,* Functional residual capacity; *RV,* residual volume; *TLC,* total lung capacity (6.0 L in an average male, 4.2 L in an average female, and 160 mL in an average 3-kg infant; see histograms on right); *VC,* vital capacity; *Vt,* tidal volume.

The volumes and capacities of the lungs are determined by many factors, including muscle strength, static-elastic characteristics of the chest wall and lungs, airway status, and patient age and cooperation. TLC is reached when the force generated by maximal voluntary contraction of the inspiratory muscles equals the inward recoil of the lung and chest wall. FRC occurs when the respiratory muscles are relaxed and no external forces are applied; it is therefore the volume at which the inward recoil of the lung is exactly balanced by the outward recoil of the chest wall (see Fig. 6.18).

Closing volume, the volume at which airways close in dependent regions of the lung, is not routinely measured but is important for our understanding of normal lung function (see: Distribution of Ventilation). Closing volume is graphically illustrated by the atelectasis observed in dependent regions of the infant lung in computed tomography scans of the chest.

In healthy children and young adults, end-expiratory lung volume during tidal volume breathing is equivalent to FRC. This is not the case in infants, who breathe at a lung volume higher than FRC. This higher volume seems to be a sensible solution to the infants' problem of having an airway closing volume that exceeds FRC. An infant maintains the expiratory lung volume higher than FRC by a combination of postinspiratory diaphragmatic activity, laryngeal adduction, and rapid respiratory rate, which minimizes the time for expiration.

The factors determining RV vary with age. In adolescents and young adults, RV occurs when the expiratory muscles cannot compress the chest wall further. In young children and older adults, RV is a function of the patency of small airways and the duration of expiratory effort.

## Measurement

Tidal volume and VC can be determined by measuring the expired volume. The measurement of FRC and RV requires another approach. Because both volumes include the air in the lungs that the patient does not normally exhale, they must be measured indirectly. One method uses the principle of dilution of the unknown volume with a known concentration of a gas that is foreign to the lung and only sparingly absorbed, such as helium. The patient breathes from a container with a known volume and concentration of helium in oxygen-enriched air. After sufficient time has elapsed for the gas in the lung to mix and equilibrate with the gas in the container, the concentration of helium in the container is remeasured. Because initial volume × initial concentration of helium = final volume × final concentration of helium, the final volume, which includes gas in the lungs, can be calculated.

The multiple breath inert gas washout method[57] also can be used to calculate lung volumes such as FRC. In addition, it provides information regarding the lung clearance index (LCI) which is now recognized to be a sensitive indicator of peripheral airway dysfunction. It also has the advantage that it can be performed in uncooperative subjects such as infants and very young children[58] (see Chapters 11 and 12).

Neither the helium dilution nor multiple breath inert gas washout methods can measure gas behind closed airways ("trapped gas") or in regions of the lung that are poorly ventilated. There is, however, a method of measuring total gas volume within the thorax that depends on the change in volume that occurs with compression of the gas when breathing against an obstruction. Practically, this measurement requires the patient to be in a body plethysmograph and to pant against a closed shutter. The change in pressure can be measured in the mouthpiece; the change in volume can be recorded with a spirometer attached to the body plethysmograph:

$$V = P\Delta V / \Delta P$$

This method has the advantage of being able to be repeated several times per minute. It has the disadvantage of including some abdominal gas in the measurement.

There have also been concerns about the validity of the plethysmographic technique in patients with severe obstructive lung disease. This issue has not yet been resolved because the technique has been reported to overestimate the lung volume in adults but underestimate the lung volume in infants with obstructive lung disease.

## Interpretation

Similar to body growth percentiles, there is a wide range of normal values for lung volumes. For example, the mean TLC for a child 140 cm tall is 3.2 L; however, the statistical range of normal (mean ± 2 SD) is 1.9 to 4.3 L. This range of normal values, when expressed as percentage predicted, is even greater for younger children or smaller lung volumes (such as RV). Owing to this wide range of normality, care must be exercised in the interpretation of lung volumes. Measurement of lung volumes is of greatest benefit when repeated over several months to assess the progress of a chronic respiratory illness and the efficacy of treatment. Healthy children grow along their lung function growth curve,[50,51] much like they grow along their growth percentiles.

The VC is one of the most valuable measurements that can be made in a functional assessment, because it is highly reproducible and has a relatively narrow range of normal values. It can be decreased by a wide variety of disease processes, including muscle weakness, loss of lung tissue, obstruction of the airway, and decreased compliance of the chest wall. VC is therefore not a useful tool to discriminate between types of lesions. Its chief role is to assign a value to the degree of impairment and to document changes that occur with therapy or time. To decide whether obstructive or restrictive lung disease is present, it is useful to measure expiratory flow rates (see Chapters 11 and 12) and to observe the pattern of abnormalities in the other lung volumes. In obstructive lung disease (e.g., asthma), the smallest lung volumes are affected first; RV increases owing to abnormally high airway resistance at low lung volumes (air trapping), and as the disease progresses, the FRC increases. Although the increase in FRC (hyperinflation) may rarely be due to loss of lung recoil, the overdistention is usually compensating for partial lower airway obstruction. When the lung volume is increased, intrathoracic airways enlarge, and widespread partial obstruction may be partially relieved by the assumption of a larger resting lung volume. Whereas the TLC is only rarely affected in obstructive disease (e.g., asthma) in children, TLC and VC are the first lung volumes to be affected in restrictive diseases of the chest wall (e.g., kyphoscoliosis) or lung (e.g., pulmonary fibrosis).

## Regional Lung Volumes

During normal breathing, different areas of the lung have different regional lung volumes; the upper airspaces are inflated more than the lower airspaces. Because static-elastic properties are fairly constant throughout the lung, these different regional lung volumes result from the gradient of pleural pressure that exists from the top to the bottom of the lung. Although gravitational forces are thought to be largely responsible, the mechanisms responsible for this pleural pressure gradient are incompletely understood. In the erect young adult lung, the pleural pressure is −8 cm $H_2O$ at the apex and only −2 cm $H_2O$ at the base. The significance of this phenomenon is that when a subject breathes in, the lowermost lung units will receive the majority of the inspired air (Fig. 6.20). This is advantageous because the majority of pulmonary blood flow also goes to the base of the lung, and thus, blood flow and ventilation patterns are more closely matched.

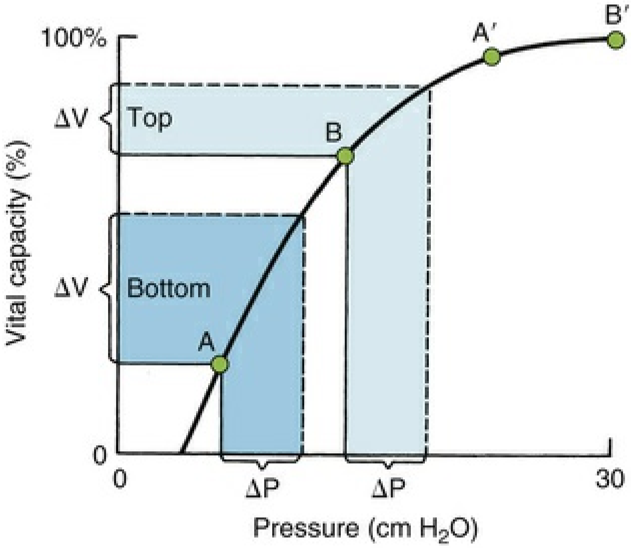

**FIG. 6.20** Pressure-volume curve of a normal lung *(heavy solid line).* At functional residual capacity, distending pressure is less at the bottom than at the top; accordingly, alveoli at the bottom (A) are smaller (i.e., lower percentage regional vital capacity) than those at the top (B). When a given amount of distending pressure (ΔP) is applied to the lung, alveoli at the bottom increase their volume (ΔV) more than alveoli at the top, owing to the varying steepness of the pressure-volume curve. When fully expanded to total lung capacity (100% VC), alveoli at the bottom (A′) are

nearly the same size as alveoli at the top (B′), because both points lie on the flat portion of the curve. (From Murray JF. *The Normal Lung*. Philadelphia: Saunders; 1976.)

# Dynamic (Flow-Resistive) Properties of the Lung

## Gas Flow Within Airways

The respiratory system must perform work to move gas into and out of the lungs. Because air moves into the lungs during inspiration and out of the lungs during expiration, and because the velocity of air flow increases from small airways to large airways, energy must be expended to accelerate the gas molecules. The respiratory system's resistance to acceleration (inertance) is minimal during quiet breathing and will not be considered further. However, inertance becomes quite significant during very high breathing rates, as occurs in high-frequency ventilation. During quiet breathing, frictional resistance to air flow accounts for one-third of the work performed during quiet breathing. The magnitude of pressure loss due to friction is determined by the pattern of flow. Flow may be laminar (streamlined) or turbulent, and which pattern exists depends on the properties of the gas (viscosity, density), the velocity of air flow, and the radius of the airway. In general, there is laminar flow in the small peripheral airways and turbulent flow in the large central airways.

The laws governing the frictional resistance to flow of gases in tubes apply to pulmonary resistance. The equation for calculating the pressure gradient required to maintain a laminar flow of air through a tube is given by Poiseuille's law:

$$P = \dot{V}\left(\frac{8l\eta}{\pi r^4}\right)$$

where P = pressure, $\dot{V}$ = flow, l = length, r = radius of the tube, and n = the viscosity of the gas. The viscosity of air is 0.000181 poise at

20°C, or only 1% that of water. Because resistance = pressure/flow, it is clear that the most important determinant of resistance in small airways will be the radius of the tube, which is raised to the fourth power in the denominator of the equation.

The pressure required to maintain turbulent flow is influenced by airway diameter and gas density and is proportional to the square of the gas velocity. The effect of gas density on turbulent flow has both therapeutic implications. Children with viral laryngotracheobronchitis have marked narrowing of the subglottic area, which greatly increases the resistance to air flow. The pressure required to overcome this increased resistance in the large airways, and hence the work of breathing can be decreased by administering a low-density gas mixture (70% helium, 30% oxygen).

## Measurement of Resistance

Resistance (R) is calculated from the equation:

$$R = \frac{\text{driving pressure}}{\text{air flow}}$$

The pressure is measured at the two ends of the system, in the case of the lung, at the mouth and at the alveoli, and the corresponding flow is recorded. Measurement of alveolar pressure presents the greatest problem. Several methods have been used to measure alveolar pressure. The most common method employs a body plethysmograph. The subject sits in an airtight box and breathes through a tube connected to a pneumotachometer, an apparatus that measures air flow. When a shutter occludes the tube and air flow ceases, the mouth pressure is assumed to be equal to the alveolar pressure. Airway resistance can then be calculated because air flow, alveolar pressure, and ambient pressure are known.

Total pulmonary resistance can be measured in infants and children by the forced oscillation technique. This measurement includes airway resistance plus the tissue viscous resistance of the lung and chest wall. Nasal resistance is also included in the measurement if the infant is breathing through the nose. Although there are theoretical objections to this technique, it has several advantages. It does not require a body plethysmograph, estimates of pleural pressure, or patient cooperation, and it can be done quickly enough to be used on ill patients. A sinusoidal pressure applied at the upper airway changes the air flow, and the ratio of pressure change to flow change is used to calculate resistance. When the forced oscillations are applied at the so-called resonant frequency of the lung (believed to be 3 to 5 Hz), it is assumed that the force required to overcome elastic resistance of the lung and the force required to overcome inertance are equal and opposite so that all of the force is dissipated in overcoming flow resistance. This technique has demonstrated that infants with bronchiolitis have about a twofold increase in inspiratory pulmonary resistance and a threefold increase in expiratory resistance.

Several new techniques have been developed that are capable of measuring lung function in infants and young children. Each has its advantages, underlying assumptions, and limitations, and these techniques are discussed in detail in Chapter 11.

## Sites of Airway Resistance

The contribution of the upper airway to total airway resistance is substantial. The average nasal resistance of infants by indirect measurements is nearly half of the total respiratory resistance, as is the case in adults. It is hardly surprising that any compromise of the dimensions of the nasal airways in an infant who is a preferential nose breather will result in retractions and labored breathing. Likewise, even mild edema of the trachea or larynx will impose a significant increase in airway resistance.

In the adult lung, about 80% of the resistance to air flow resides in airways greater than 2 mm in diameter. The vast number of small peripheral airways provides a large cross-sectional area for flow and therefore contributes less than 20% to the airway resistance. Thus, these airways may be the sites of disease that may severely impair ventilation of distal airspaces without appreciably altering the total airway resistance. In the infant lung, however, small peripheral airways may contribute as much as 50% of the total airway resistance, and this proportion does not decrease until about 5 years of age. Thus, the infant and young child are particularly severely affected by diseases that affect the small airways (e.g., bronchiolitis).

## Factors That Affect Airway Resistance

Airway resistance is determined by the diameter of the airways, the velocity of air flow, and the physical properties of the gas breathed. The diameter is determined by the balance between the forces tending to narrow the airways and the forces tending to widen them. One of the forces tending to narrow the airways is exerted by the contraction of bronchial smooth muscle. The neural regulation of bronchial smooth muscle tone is mediated by efferent impulses through autonomic nerves. Sympathetic impulses relax the airways, and the parasympathetic impulses constrict them. Bronchi constrict reflexly from irritating inhalants (e.g., sulfur dioxide and some dusts); by arterial hypoxemia and hypercapnia; by embolization of the vessels; by cold; and by some vasoactive mediators (e.g., acetylcholine, histamine, bradykinin, and leukotrienes). They dilate in response to an increase in systemic blood pressure through baroreceptors in the carotid sinus and to beta sympathomimetic agents such as salbutamol (selective beta$_2$ agonist), isoproterenol (beta$_1$ and beta$_2$ agonist), and epinephrine (nonselective alpha and beta agonist). The large airways are probably in tonic contraction in health, because in unanesthetized adults, atropine or isoproterenol will decrease airway resistance.

Airway resistance changes with lung volume but not in a linear manner. Increasing the lung volume to above FRC only minimally decreases airway resistance. In contrast, as lung volume decreases from FRC, resistance rises dramatically and approaches infinity at RV. Although alterations in bronchomotor tone play a role, it is the decrease in lung elastic recoil as lung volume declines that is the predominant mechanism for the change in airway resistance. The recoil of the lung provides a tethering or “guy wire” effect on the airways that tends to increase their diameter. Children of different ages will have different airway resistances owing to the different sizes of their lungs. Therefore, the measurement of airway resistance or its reciprocal (airway conductance) is usually corrected by dividing the airway conductance by the simultaneously measured lung volume. The resultant specific airway conductance is remarkably constant regardless of the subject's age or height.

## Dynamic Airway Compression

During a forced expiration, both the pleural and the peribronchial pressures become positive and tend to narrow the airways; forces tending to keep airways open are the intraluminal pressure and the tethering action of the surrounding lung. During active expiration, however, the intraluminal pressure must decrease along the pathway of air flow from the alveoli to the mouth, where it becomes equal to atmospheric pressure. Therefore, at some point in the airway, intraluminal pressure must equal pleural pressure, the equal pressure point (EPP). Downstream from the EPP, pleural pressure exceeds intraluminal pressure and thus is a force that tends to narrow the airways. Indeed, during periods of maximum expiratory flow, pleural pressure exceeds the critical closing pressure of the airways, which become narrowed to slits. Despite the cartilaginous support of the larger airways, the membranous portion of the wall of the trachea and large bronchi invaginates under pressure to occlude the airways. Maximum flow under this circumstance is therefore determined by the resistance of the airways located upstream from the EPP, and the driving pressure is the difference between the alveolar pressure and the pressure at the EPP. In disease states in which there is increased airway resistance, the EPP moves toward the alveoli because of the greater intraluminal pressure drop. Thus, small airways are compressed during forced expiration with severe flow limitation. With the measurement of pressure-flow and flow-volume curves during forced expiration, it is possible to calculate resistance upstream and downstream from the point of critical closure, or EPP. Increasing the lung volume increases the tethering action of the surrounding lung on the airways, and therefore close attention must be paid to the lung volume at which resistance measurements are made during these studies.

## Work of Breathing

*Work* is defined as the force over distance or three-dimensionally as pressure during changes in volume. Thus, the work performed by the respiratory pump is defined by the volume changes of the lungs when the respiratory muscles generate a given pressure. The volume-pressure relationships of the respiratory system depend on properties of the lung and chest wall tissues or the ease with which the airways allow the passage of air. A substantial portion of the pressure generated by the respiratory muscles is applied to produce reversible rearrangements of the structure of the alveolar gas-liquid interface and the fibrous network of the lungs. Another large portion of the effort of the respiratory muscles is directed at producing rearrangements or interactions that are not reversible. The energy spent in such an effort is directly transformed into heat, which is then dissipated into the atmosphere or carried away by the circulating blood. The magnitudes of the work and the pressures derived from these processes generally bear a relationship to the rate of gas flow in and out of the lungs. In this regard, the respiratory system exhibits a resistive behavior for which the driving pressure determines the flow of air. Both the elastic and the resistive components of the work of breathing are usually increased in children with respiratory disease.

Respiratory work normally accounts for about 3% of an individual's total oxygen consumption. This work is increased in various diseases, and establishing a diagnosis and formulating a therapy in these patients is almost always simplified when the clinician distinguishes between conditions that affect primarily the elastic (restrictive respiratory disease) and resistive (obstructive respiratory disease) behaviors of the respiratory system.

# Distribution of Ventilation

The distribution of ventilation is influenced by several factors in the normal lung. The pleural pressure gradient results in a greater amount of the tidal volume going to the dependent areas of the lung (see Fig. 6.20). In addition, the rate at which an area of the lung fills and empties is related to both regional airway resistance and compliance. A decrease in an airway's lumen increases the time required for air to reach the alveoli; a region of low compliance receives less ventilation per unit of time than an area with high compliance. The product of resistance and compliance (the “time constant”) is approximately the same in health for all ventilatory pathways. The unit of this product is time. Note the following:

$$\text{Resistance} = \frac{\text{pressure}}{\text{flow}} = \frac{cm\ H_2O}{L/sec}$$

and

$$Compliance = \frac{\Delta volume(L)}{\Delta pressure(cm\ H_2O)}$$

The product, then, is a unit of time, analogous to the time constant in an electrical system, which represents the time taken to accomplish 63% of the volume change.

As mentioned earlier in the chapter, peripheral airways contribute little to overall airway resistance after 5 years of age. However, in the presence of small airway disease, some areas of the lung have long-time constants, but those of others are normal. This is particularly evident as the frequency of respiration increases. With increasing frequency, air goes to those areas of the lung with short time constants. These areas then become relatively overdistended, and a greater transpulmonary pressure is required to inspire the same volume of air, because alveoli in these relatively normal areas are reaching their elastic limit. Thus, a decreased dynamic compliance with increasing frequency of respiration has been used as a test of small airway disease and indeed may be the only mechanical abnormality detectable in the early stages of diseases such as emphysema and cystic fibrosis.

Airway closure occurs in dependent areas of the lung at low lung volumes. The lung volume above RV at which closure occurs is called the *closing volume.* In infants, very young children, and older adults, airway closure occurs at FRC and therefore is present during normal tidal breathing.[39] This results in intermittent inadequate ventilation of the respective terminal lung units and leads to abnormal gas exchange, notably to a lower $PaO_2$ seen in these age groups.

# Pulmonary Circulation

## Physiologic Classification of Pulmonary Vessels

The pulmonary circulation is the only vascular bed to receive the entire cardiac output. This unique characteristic enables the pulmonary vascular bed to perform a wide variety of homeostatic physiologic functions. It provides an enormously large (~120 to 130 $m^2$) yet extremely thin surface for gas exchange, filters the circulating blood, controls the circulating concentrations of many vasoactive substances, and provides a large surface area for the absorption of lung liquid at birth. The nomenclature of the pulmonary vessels is at times confusing because the anatomic classification of the vessels often does not correspond to their physiologic role.

The anatomic and histologic characteristics of the pulmonary vasculature are described earlier in the chapter. It is important to understand that pulmonary vessels have been classified physiologically as extra-alveolar and alveolar vessels, fluid-exchanging vessels, and gas-exchanging vessels. When the outside of a vessel is exposed to alveolar pressure, it is classified as an alveolar vessel (capillaries within the middle of the alveolar septum), whereas extra-alveolar vessels (arteries, veins, and capillaries at the corner of alveolar septa) are intrapulmonary vessels that are subjected to a more negative pressure resulting from and approximating pleural pressure. The diameter of the extra-alveolar vessels is therefore greatly affected by lung volume, expanding as inspiration occurs. Although extra-alveolar vessels and alveolar vessels are subjected to different mechanical pressures, they are both classified as fluid-exchanging vessels because both leak water and protein and can contribute to the production of pulmonary edema. The anatomic location of gas-exchanging vessels is unclear but is likely limited to the capillaries and smallest arterioles and venules.

## Pulmonary Vascular Pressures

The pressure within the pulmonary circulation is remarkably low considering that it receives the entire cardiac output (5 L/min in the adult human). Beginning a few months after birth, pulmonary arterial pressures are constant throughout life, with the average mean pulmonary arterial pressure being 15 mm Hg and the systolic and diastolic pressures being 22 and 8 mm Hg, respectively. The pulmonary venous pressure is minimally higher than the left atrial pressure, which averages 5 mm Hg. The pressure within human lung capillaries is unknown, but work in isolated dog lungs suggests it is 8 to 10 mm Hg, approximately halfway between the mean arterial and venous pressures. These values refer to pressures at the level of the heart in the supine position; because of gravity, pulmonary arterial pressures are near zero at the apex of the upright adult lung and close to 25 mm Hg at the base. Depending on their location, vessels have different pressures on their outside walls. As defined previously, the alveolar vessels are exposed to alveolar pressure, which fluctuates during the respiratory cycle, but will average out close to zero. In contrast, the extra-alveolar vessels are exposed to a negative fluid pressure on their outer walls, estimated to be between −6 and −9 cm $H_2O$. The pressure on the outside of the pulmonary vessel is not a trivial matter, because the transmural pressure (inside pressure–outside pressure), rather than the intravascular pressure, is the pertinent hydrostatic pressure influencing vascular distention and the transvascular movement of water and protein (see Chapter 36).

## Pulmonary Vascular Resistance

The resistance to blood flow through the lungs can be calculated by dividing the pressure across the lungs by the pulmonary blood flow.

$$R = \frac{mean\ PA\ pressure - mean\ LA\ pressure}{pulmonary\ blood\ flow}$$

A decrease in resistance to blood flow can occur only through (1) an increase in the blood vessels' lumenal diameters or (2) an increase in the number of perfused vessels. Each of these will contribute to an increase in the cross-sectional diameter of the pulmonary vascular bed. The diameter of an already open pulmonary vessel can be increased by decreasing the muscular tone of the vessel wall (e.g., with a vasodilating agent) or by increasing the transmural pressure (e.g., through increased pulmonary arterial or left atrial pressure). Previously unperfused pulmonary vessels may be opened up (“recruited”) when their transmural pressure exceeds their critical opening pressure. This occurs when intravascular pressures are raised or when a vasodilator has decreased the vessels' critical opening pressure. An increase in cardiac output decreases the calculated pulmonary vascular resistance (PVR). This is important to remember when assessing vasodilating drugs; studies have been performed in which drugs were found to increase cardiac output substantially so that the calculated PVR falls. This decrease in resistance does not ensure that a particular drug has any direct vasodilating action at all, because the entire decrease in PVR may have resulted from its cardiac effects.

The interrelationship between lung volume and PVR is complex and is influenced by pulmonary blood volume, cardiac output, and initial lung volume. The principal reason for this complex relationship is that a change in lung volume has opposite effects on the resistances of the extra-alveolar and alveolar vessels. As the lung is inflated, the radial traction on the extra-alveolar vessels increases their diameter, whereas the same increase in lung volume increases the resistance to flow through the alveolar vessels (which constitutes 35% to 50% of the total PVR). It is reasonable to say, however, that PVR is at its minimum at FRC, and any change in lung volume (increase or decrease) will increase the PVR (Fig. 6.21).

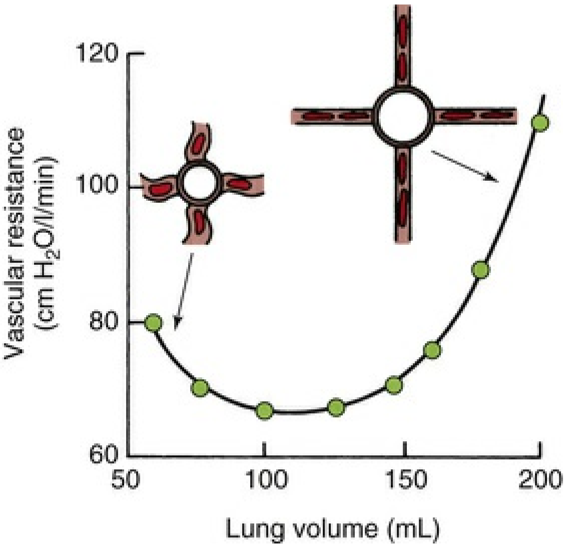

**FIG. 6.21** Effect of lung volume on pulmonary vascular resistance when the transmural pressure of the capillaries is held constant. At low lung volumes, resistance is high because the extra-alveolar vessels become narrow. At high volumes, the capillaries are stretched, and their caliber is reduced. (From West JB. *Respiratory Physiology—The Essentials.* Baltimore: Williams & Wilkins; 1974.)

Active changes in PVR can be mediated by neurogenic stimuli, vasoactive compounds, or chemical mediators. The normal adult pulmonary circulation appears to be maximally dilated, since no stimulus has been found that can further dilate the pulmonary vessels. In contrast, the neonatal lung or the vasoconstricted adult lung vasodilates in response to a variety of agents, including nitric oxide, acetylcholine, β-agonist drugs, bradykinin, prostaglandin E, and prostacyclin.

The pulmonary circulation can undergo significant vasoconstriction, which is surprising in view of the paucity of muscle in postnatal lung vessels. Hypoxia is the most common potent pulmonary vasoconstricting agent. Hypoxic vasoconstriction, which occurs when the alveolar $P_{O_2}$ falls below 50 to 60 mm Hg, is a local response independent of neurohumoral stimuli. Although many suggestions have been made, the exact mechanism of hypoxia-induced vasoconstriction is unknown. Acidosis acts synergistically with hypoxia to constrict the pulmonary vessels; however, it is unlikely that $CO_2$ alone has any direct effect on the pulmonary circulation in humans. Stimulation of the pulmonary sympathetic nerves results in a weak vasoconstrictive response in the dog lung but little or no response in the normal human adult pulmonary circulation. Vasoactive substances (e.g., histamine, fibrinopeptides, prostaglandins of the F series, and leukotrienes) are capable of constricting the pulmonary vascular bed. It had been believed that vasoconstriction in the pulmonary circulation took place predominantly, if not exclusively, within the arterial section of the vascular bed. However, it has been demonstrated that other regions of the bed may narrow in response to stimuli. For example, hypoxia can constrict the pulmonary venules of newborn animals and might increase resistance within the capillary bed by inducing constriction of myofibroblasts that are located within the interstitium of the alveolar-capillary membrane. The fetal and neonatal pulmonary circulation contains a large amount of smooth muscle, which enhances the response to vasoconstrictive stimuli.

## Distribution of Blood Flow

Blood flow is uneven within the normal lung and is influenced by the vascular branching pattern and gravity that when standing results in more blood flow being directed to the dorsal caudal regions and less to the cephalad regions. Gravitational forces are largely responsible for the increasing flow from apex to base because the intravascular pressure of a given blood vessel is determined by the pulmonary arterial pressure immediately above the pulmonary valve and the blood vessel's vertical distance from the pulmonary valve. Thus, with increasing height above the heart, the pulmonary arterial pressure decreases and less perfusion occurs. The opposite occurs for vessels located in the lung bases, and together these gravitational effects are responsible for a pressure difference of approximately 23 mm Hg between apical and basal pulmonary arteries.

These regional differences in lung perfusion are best understood in terms of West's zones of perfusion (Fig. 6.22). West's zone I occurs when mean pulmonary arterial pressure is less than or equal to alveolar pressure, and as a result, no blood flow occurs (except perhaps during systole). Zone I conditions are present in the apices of some upright adults and result in unperfused yet ventilated lung units (alveolar dead space). Moving down from the lung apices, pulmonary arterial pressure becomes greater than alveolar pressure, with the latter being greater than venous pressure. These are zone II conditions, and blood flow is determined by the difference between arterial and alveolar pressures and is not influenced by venous pressure; an appropriate analogy would be that of a vascular "waterfall," in which the flow rate is independent of the height of the falls. In zone III, left atrial pressure exceeds alveolar pressure, and flow is determined in the usual manner (i.e., by the arterial-venous pressure gradient).

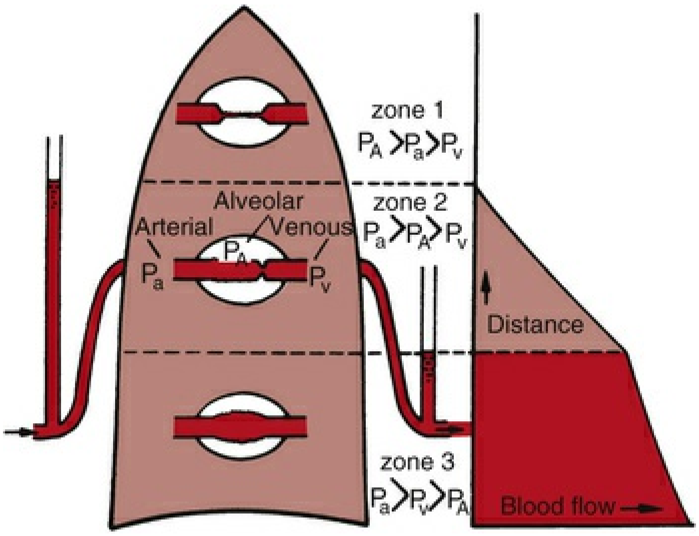

**FIG. 6.22** Model to explain the uneven distribution of blood flow in the lung based on the pressures affecting the capillaries. $P_a$, Pulmonary arterial pressure; $P_A$, alveolar pressure; $P_V$, pulmonary venous pressure.

(From West JB, Dollery CT, Naimark A. Distribution of blood flow in isolated lung. Relation to vascular and alveolar pressures. *J Appl Physiol.* 1964;19:713.)

## Methods of Evaluating the Pulmonary Circulation

The chest radiograph is the most basic noninvasive and nonquantitative tool for determining the possible presence of pulmonary vascular disease. Prominence of the pulmonary outflow tract occurs when the elevated pressure distends the elastic main pulmonary arteries. Vascular markings may be increased or decreased; the former occurs when there is elevated pulmonary blood flow or volume without vascular remodeling, and the latter occurs when there is distal "pruning" of the vessel's image when vascular remodeling has occurred. Computerized axial tomography and magnetic resonance imaging provide greater detail of the right ventricle and pulmonary vessels.

Echocardiography is able not only to assess the structure and function of the right ventricle but also to provide a reasonable estimate of right ventricular pressure by assessing the velocity of the small retrograde flow through the tricuspid valve that frequently occurs in significant pulmonary hypertension. Quantitative assessment of regional pulmonary blood flow can be made with intravenous injections of macroaggregates of albumin labeled with technetium$^{99m}$. The macroaggregates occlude a very small portion of the pulmonary vascular bed. The amount of regional blood flow can be determined by imaging the lungs with a large field-of-view gamma camera and determining the count rate with a computer. The perfusion lung scintigram can be combined with a ventilation scintigram performed with either a radioactive gas (e.g., xenon 133 or krypton$^{81m}$) or a radiolabeled ($^{99m}$Tc–diethylenetriamine-pentacetic acid) aerosol that is distributed like a gas.

Regional pulmonary angiography further delineates localized disturbance in blood flow, although the procedure requires cardiac catheterization. Direct measurements of pulmonary artery and pulmonary artery occlusion ("wedge") pressures add further information. Occasionally, drugs can be infused into the pulmonary artery to evaluate the potential reversibility of pulmonary hypertension.

Further details regarding the pathobiology and treatment of pulmonary hypertension are available elsewhere[59,60] and in Chapter 35.

## Muscles of Respiration

The importance of the muscles of respiration derives from the fact that these muscles, similar to the myocardium, can fail under abnormal circumstances and can induce or contribute to an impending or existing ventilatory failure.[61]

The principal muscle of respiration is the diaphragm, a thin musculotendinous sheet that separates the thoracic from the abdominal cavity. In adults, its contraction causes descent of its dome and aids in elevation of the lower ribs, the latter referred to as the "bucket handle effect." Some work indicates that the diaphragm has two separate but related functions. The costal part of the diaphragm (largely innervated by C5) acts to stabilize and elevate the lower rib cage during contraction. The vertebral (crural) portion (largely innervated by C3), a much thicker muscle, descends with contraction and is largely responsible for the volume change that occurs.

Three anatomic characteristics of the infant's chest wall and diaphragm lead to decreased diaphragmatic efficiency and a lower fatigue threshold. First, the infant's chest wall is highly compliant[56] so that when there is respiratory disease there is increased work. Second, the diaphragm is less effective as a result of its higher position within the chest and less apposition to the rib cage. Third, the infant's ribs are more horizontal, which lessens the bucket handle effect.[62]

Other skeletal muscles located in the chest or abdominal wall (e.g., the intercostals, scalenes, and abdominal muscles) can play an important role in ventilation. During normal breathing, most of the accessory muscles are silent. However, during abnormal conditions or disease states, these muscles are recruited to stabilize the chest or abdominal wall so that the diaphragm may be more efficient. In addition, it has been demonstrated that the external intercostal muscles contract in acute asthmatic attacks not only during inspiration but also during expiration; this contraction maintains a higher lung volume and hence increases airway diameter. When airways are occluded during inspiration, abdominal muscles contract powerfully during expiration, pushing the abdominal contents and diaphragm toward the thoracic cavity. This action lengthens diaphragmatic fibers and enhances the capability of the diaphragm to generate force during the subsequent inspiration (length-tension curve).

The upper airways must be kept patent during inspiration, and therefore, the pharyngeal wall muscles, genioglossus, and arytenoid muscles are properly considered muscles of respiration. There is an increase in neural output to these muscles immediately before diaphragmatic contraction during inspiration. The newborn also contracts these muscles during expiration to provide an expiratory outflow resistance and thus keeps end-expiratory volume greater than the FRC.

Respiratory muscles, whether the diaphragm, upper airway, intercostal, or abdominal muscles, are not homogeneous muscles in terms of their cellular structure, blood supply, metabolism, and recruitment patterns. Adult mature skeletal muscles have a mixture of fibers, and respiratory muscles are no different. The adult diaphragm, for instance, is made of fast- and slow-twitch fibers. Slow-twitch fibers are oxidative, and fast-twitch fibers are either glycolytic or moderately oxidative. Slow-twitch fibers are fatigue resistant—they are recruited first during a motor act; they generate low tensions; and they usually have a higher capillary/fiber ratio than fast fibers. Fast-twitch fibers can be either fatigue resistant (fast, moderately oxidative) or fast fatiguing (fast glycolytic); they are recruited during motor acts that require large force output. Thus, during normal quiet breathing, it is presumed that only the slow-twitch fibers in the diaphragm are active. In contrast, at the height of an acute attack of croup, asthma, or bronchiolitis during which muscle contractions are strong, both fiber types can be active, with the fast fibers generating the bulk of the force.

Muscle fiber composition, innervation, and metabolism are different in early life. The process of muscle fiber differentiation and interaction with the central nervous system is a continuous process, starting *in utero* and continuing postnatally. For example, slow oxidative fibers increase *in utero* and postnatally, whereas fast glycolytic fibers decrease postnatally. Polyneuronal innervation transforms into one motoneuron = one muscle fiber—the adult type of innervation—postnatally. Whether the young infant's ability to resist muscle fatigue is jeopardized by premature muscle fiber composition, innervation, and metabolism is not known and deserves further investigation.

Respiratory muscle fatigue may arise from central drive fatigue, neural transmission fatigue, contractile fatigue, or a combination of these three phenomena. Many factors predispose respiratory muscles to fatigue. Factors that increase fuel consumption (e.g., increased loads with disease); limit fuel reserves (e.g., malnutrition); alter acid-base homeostasis (e.g., acidosis); modify the oxidative capacity, glycolytic capacity, or both of the muscle (e.g., decreased activity of the muscle and possible atrophy after prolonged artificial ventilation); and decrease the oxygen availability to the muscle (e.g., anemia, low cardiac output states, hypoxemia) all predispose the diaphragm to failure. Reactive oxygen species (free radicals) produced by the contracting diaphragm are also thought to play a role in causing fatigue, particularly in conditions of ischemia/reperfusion and sepsis. In addition, changes in the external milieu of the muscle cell (e.g., low phosphate levels or the presence of certain drugs such as anesthetics) can limit the contractile ability and lead to premature muscle fatigue.

Diaphragmatic muscle function can be assessed clinically by observing the movements of the abdominal wall. During normal inspiration and with the contraction of the diaphragm, the abdominal contents are pushed away from the thorax. Because the abdominal wall is normally compliant during inspiration, the abdominal wall moves out to accommodate the increased pressure from the contracting diaphragm. With diaphragmatic fatigue, weakness, or paralysis, it is possible to observe an inward motion of the abdominal wall. Through the action of other respiratory muscles (intercostals), a drop in pressure occurs in the thorax during inspiration. Because of the “passive” behavior of the fatigued diaphragm, this pressure drop is transmitted to the abdomen; hence, the movement of the abdominal contents toward the thoracic cavity.

The highly compliant chest wall in the newborn infant limits its expansion during inspiration. The chest wall becomes even more unstable during REM sleep, when intercostal muscle activity is inhibited and the rib cage is more prone to distortion. This creates an added load and the potential for diaphragmatic fatigue.

A patient's respiratory muscle strength can be measured using various techniques,[63] all of which are effort dependent. These include maximum inspiratory and expiratory pressures, sniff pressures, and indirectly by maximal cough flows. If the airway is occluded during normal breathing, the infant,[64] child, and adult diaphragm are all capable of generating airway pressures of greater than 100 cm $H_2O$ during a maximal inspiratory effort. In the laboratory, respiratory muscle function can be assessed in more detail (e.g., using electromyographic measurements during repeated stimulation of the phrenic nerve). The measurement of transdiaphragmatic pressure (Pdi) by placing balloon catheters just above (esophageal) and below (gastric) the diaphragm can provide a surrogate measure for muscle strength and susceptibility for fatigue, the time tension index (TTI):

$$\mathrm{TTI} = (\mathrm{P_{DI}}/\mathrm{P_{DI}}_{max}) * (\mathrm{T_I}/\mathrm{T_{TOT}})$$

PDI = mean transdiaphragmatic pressure
$\mathrm{PDI}_{max}$ = maximal transdiaphragmatic pressure
TI = inspiratory time
TTOT = respiratory cycle time

In adults, when the TTI is less than 0.1, it is unlikely that diaphragmatic fatigue will occur.

A less invasive measure involves measuring inspiratory pressures at the mouth instead of across the diaphragm. In this situation,

$$\mathrm{TTI} = (\mathrm{PI}_{mouth}/\mathrm{Pmax}_{mouth}) * (\mathrm{T_I}/\mathrm{T_{TOT}})$$

The caveat for using mouth pressures is that it provides a measurement of force generation during the duty cycle by all respiratory muscles and not just the diaphragm. A TTI > 0.15 has been used to predict unsuccessful extubations in ventilated children.

To consider the main respiratory muscles—the diaphragm and the intercostal muscles—as the only respiratory muscles for breathing is insufficient, especially during stressful conditions or disease states. A number of muscles, such as the alae nasi, pharyngeal wall muscles, genioglossus, posterior cricoarytenoid, and thyroarytenoid, can play major roles in airway patency and hence in ventilatory output. Data indicate that upper airway muscles are strongly recruited during obstructive disease or during inspiratory occlusion, and that blood flow increases considerably to some of them (e.g., genioglossus). How prone these muscles are to fatigue under increased loads is unknown. How different these muscles are in terms of their structure, metabolism, and function in the neonate versus the adult is unclear and needs further research.

Because of the number of muscles involved, their location, and their function, the coordination of respiratory muscles becomes increasingly complex. The motor act of respiration should no longer be viewed as the result of one or two muscles contracting during inspiration and relaxing during expiration. At rest and even more so during disease states, the active coordination of various muscles becomes functionally very important. Defecation, sucking, and talking all involve the activation of several muscles that are shared by the respiratory apparatus for generating adequate ventilation. In some cases, obstructive apneas can actually be the result of muscle incoordination, with the diaphragm contracting when upper airway muscles that normally hold the airway open are relaxed.

# Gas Exchange

The vital process of gas exchange occurs in the terminal respiratory unit. The previous sections of this chapter deal with the problems of moving air and blood to and from these gas-exchanging units. This section focuses on the fate of gas once it is introduced into the lungs, how it is transferred from the alveolar space to the bloodstream, and how ventilation and perfusion are matched.

In Fig. 6.23, the partial pressures of oxygen and carbon dioxide are depicted at various stages of the pathway from ambient air to the tissues. Because nitrogen is inert, changes in its partial pressure ($P_{N_2}$) in the gas phase depend on changes in the partial pressures of oxygen and carbon dioxide, gases that are utilized and excreted, respectively. In contrast, $P_{N_2}$ in blood and tissue is identical because nitrogen is inert. The rather complex influences of dead space, alveolar ventilation, ventilation-perfusion relationships, and tissue metabolism on the partial pressures of oxygen and carbon dioxide are discussed in some detail, and frequent reference to Fig. 6.23 is useful in clarifying some of the concepts.

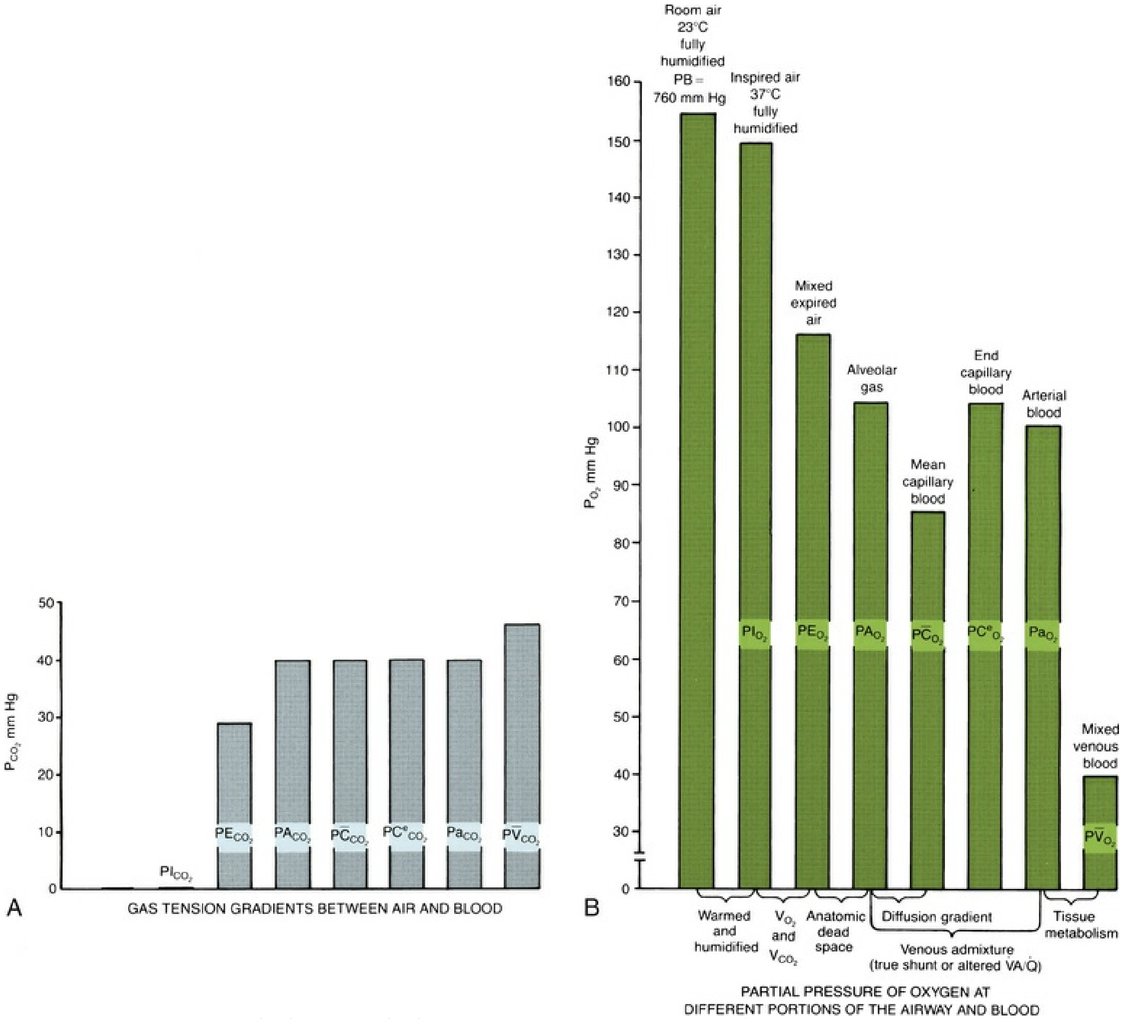

**FIG. 6.23** (A) and (B) Partial pressures of oxygen and carbon dioxide in different portions of the airway and blood.

## Alveolar Ventilation

One component of the $V_T$ is the anatomic dead space, $V_D$ (consisting of the nose, mouth, pharynx, larynx, trachea, bronchi, and bronchioles), where no significant exchange of oxygen and carbon dioxide with blood takes place. The other component of the $V_T$, $V_A$, undergoes gas exchange in the alveoli. Alveolar ventilation per minute is measured by the following equation:

$$V_A = V_T - V_D$$

In practice, $V_D$ is difficult to measure, so the alveolar ventilation equation is used. Since all expired $CO_2$ comes from the alveolar gas,

$$V_{CO_2} = V_A \times \%CO_2/100 \text{ or}$$
$$V_A = V_{CO_2} \times 100/\%CO_2.$$

The $\%CO_2/100$ is the fractional concentration of $CO_2$ in the alveolar gas ($F_{ACO_2}$), which can be measure by a rapid $CO_2$ analyzer. $F_{ACO_2}$ can be converted to partial pressure of $CO_2$ by multiplying by $P_B$, 47 mm Hg. Thus,

$$V_A = V_{CO_2}/P_{ACO_2}$$

In normal subjects, the $P_{CO_2}$ in alveolar gas ($P_{ACO_2}$) is essentially the same as the arterial $P_{CO_2}$ ($P_{aCO_2}$), which can be used to determine alveolar ventilation. Note the important relationship between alveolar ventilation and $P_{aCO_2}$. When $V_A$ is halved, then $P_{aCO_2}$ must double at a constant $V_{CO_2}$; when $V_A$ is doubled, $P_{aCO_2}$ is halved at a constant $V_{CO_2}$.

## Dead Space

The volume of the conducting airways is called the anatomic dead space ($V_{Danat}$) and is approximately 25% of each $V_T$. Anatomic dead space in milliliters is roughly equal to the weight of the subject in pounds (for a 7-pound baby, 7 or 8 mL; for an adult weighing 150 pounds, 150 mL). In the normal premature infant, anatomic dead space is slightly higher than 30%. In practice, anatomic dead space is seldom measured but may be obtained by Fowler's method, which requires that a single breath of oxygen be inspired. On expiration, both the volume of expired gas and the percentage of nitrogen are measured. The first portion of the expired gas comes from the dead space and contains little or no nitrogen. As the breath is expired, the percentage of nitrogen increases until it “plateaus” at the alveolar concentration. By assuming that all the initial part of the breath comes from the anatomic dead space and all the latter portion from the alveoli, the anatomic dead space can be calculated. The same measurements can be made by monitoring the expired carbon dioxide concentration. In practice, anatomic dead space is difficult to define accurately, because it depends on lung volume (greater at large lung volumes when the airways are more distended) and on body position (smaller in supine position).

Physiologic dead space may be measured by making use of the argument originally developed by Bohr. Since all of the expired $CO_2$ ($F_{ECO_2}$) comes from the alveolar gas ($F_{ACO_2}$) and none from the dead space,

$$V_T \times F_{ECO_2} = V_A \times F_{ACO_2}.$$

And since $V_A = V_T - V_D$, then

$$V_T \times F_{ECO_2} = (V_T - V_D) \times F_{ACO_2}$$

and

$$V_D/V_T \cong F_{ACO_2} - F_{ECO_2}/F_{ACO_2}$$

And since the partial pressure of a gas is proportional to its fractioned concentration (F),

$$V_D/V_T = P_{ACO_2} - P_{ECO_2}/P_{ACO_2} \text{ (Bohr equation)}$$

Or, since alveolar $P_{CO_2}$ and arterial $P_{CO_2}$ are identical in normal subjects,

$$VD/VT = PACO_2 - PECO_2/PACO_2$$

It is now quite clear that VDphys must be defined according to the gas being measured. Because oxygen is more diffusible in the gas phase than is carbon dioxide, physiologic dead space using oxygen or various inert gases is different from the $CO_2$ dead space. However, VDphys measurements using $CO_2$ are helpful in assessing patients, because they reflect the portion of each breath that participates in gas exchange, particularly with respect to $CO_2$. An elevated VDphys indicates that areas of the lung are being underventilated in relation to the amount of blood flowing through the region.

From the foregoing discussion, it is apparent that a VT value must be chosen that will allow adequate alveolar ventilation. For example, an adult might breathe 60 times per minute with a VT of 100 mL for a minute ventilation of 6 L. Nevertheless, alveolar ventilation under these circumstances may be inadequate, because the dead space is primarily ventilated. In selecting suitable volumes and rates for patients on respirators, it is useful to approximate normal values and to consider adequate alveolar ventilation rather than total ventilation. A discussion of high-frequency ventilation is beyond the scope of this chapter.

## Alveolar Ventilation and Alveolar Gases

The amount of alveolar ventilation per minute must be adequate to keep the alveolar $PO_2$ and $PCO_2$ at values that will promote the escape of carbon dioxide from venous blood and the uptake of oxygen by pulmonary capillary blood. In healthy patients at sea level, this means that $PAO_2$ is approximately 105 to 110 mm Hg and $PACO_2$ is 40 mm Hg (Fig. 6.24).

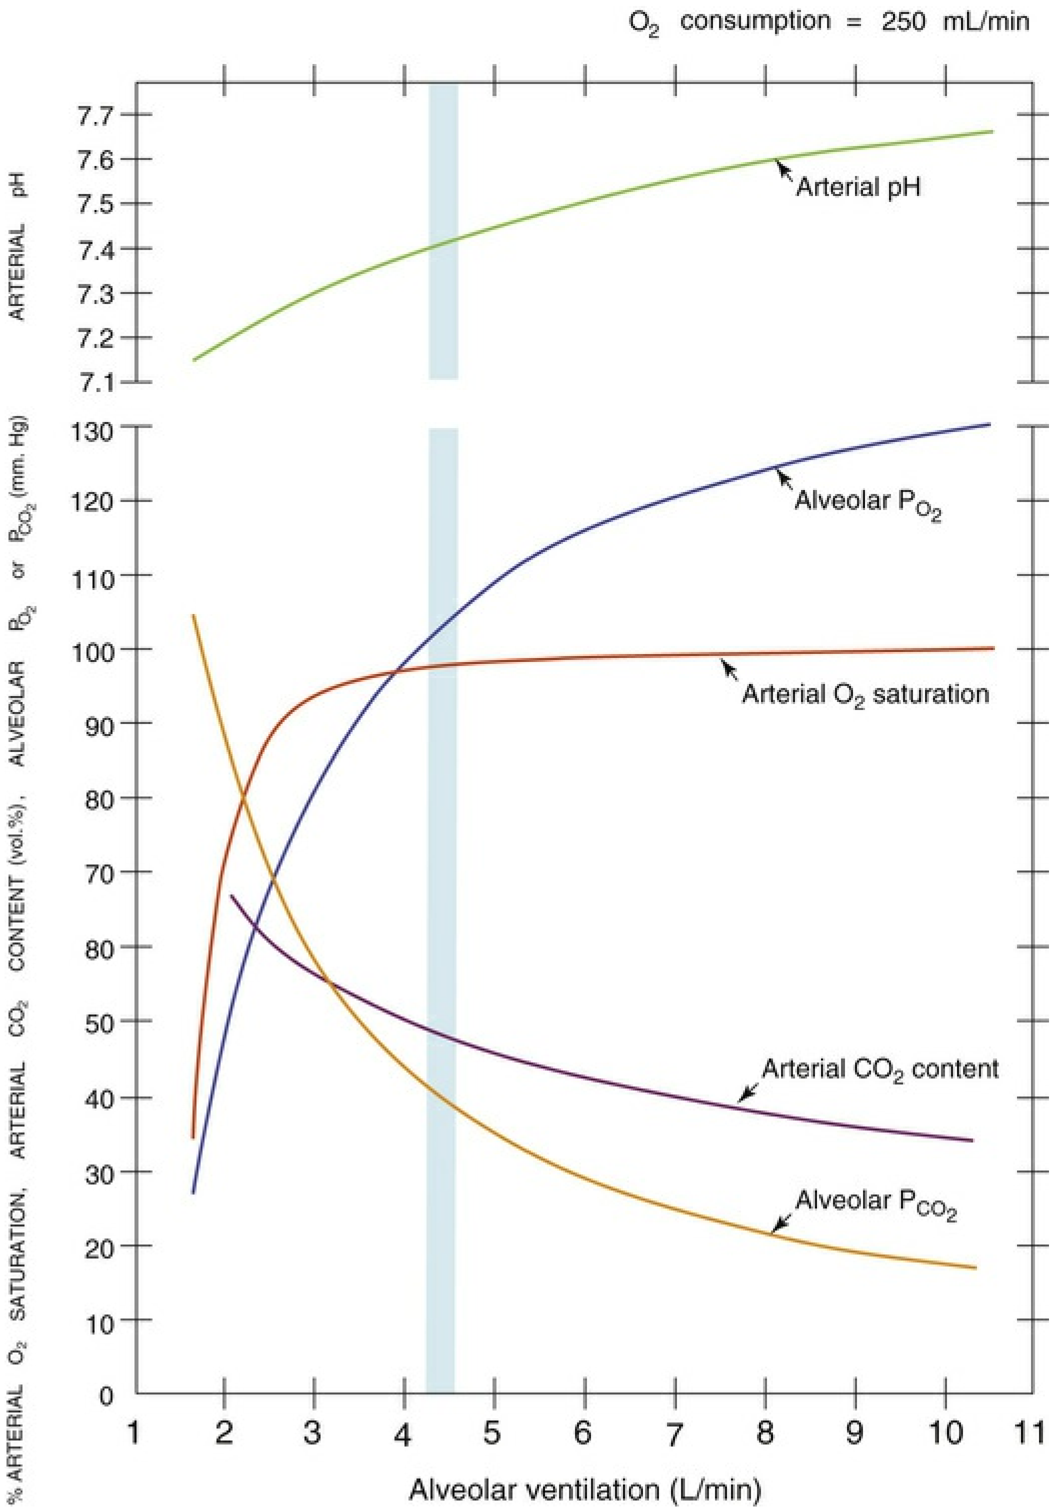

**FIG. 6.24** The effect of changing alveolar ventilation on alveolar gas and arterial blood oxygen, carbon dioxide, and pH. (From Comroe Jr JH, Forster RE II, Dubois AB, et al. *The Lung,* 2nd ed. Chicago: Year Book Medical; 1962.)

Arterial $P_{O_2}$ is markedly affected by the presence of right-to-left shunts, and therefore it is not a good measurement of the adequacy of pulmonary ventilation. $PaCO_2$ is minimally affected in the presence of shunts because $Pv–CO_2$ is 46 mm Hg and $PaCO_2$ is 40 mm Hg. If one third of the cardiac output is shunted, this raises $PaCO_2$ to only 42 mm Hg. Thus, the arterial $PCO_2$ is the optimum measurement of the adequacy of alveolar ventilation. When alveolar ventilation halves, $PaCO_2$ doubles; when alveolar ventilation doubles, $PaCO_2$ halves. Hyperventilation is defined as a $PaCO_2$ less than 35 mm Hg, and hypoventilation as a $PaCO_2$ greater than 45 mm Hg. Hypoventilation can occur as a result of respiratory center malfunction (e.g., congenital hypoventilation syndrome) or depression (e.g., anesthetics) or when there is profound disease involving the lung, chest wall, or respiratory muscles such that effective alveolar ventilation cannot be maintained. Inspired air has a fraction of inspired oxygen ($FIO_2$) of 0.2093, and it is "diluted" in the alveoli by the FRC of air containing carbon dioxide and water vapor, so the $PO_2$ in alveolar gas must be less than that of the inspired air ($PIO_2$; see earlier discussion of Dalton's law). $PAO_2$ must be calculated from the alveolar air equation. When oxygen consumption equals carbon dioxide production, then,

$$PAO_2 = PIO_2 - PACO_2$$

$$PIO_2 = 0.2093 \times (PB - 47 \text{ mm Hg}) = 150 \text{ mm Hg}$$

If $PACO_2$ is 40 mm Hg, then $PAO_2$ is 110 mm Hg. Usually, the respiratory exchange ratio (R) is 0.8, or more oxygen is consumed than carbon dioxide eliminated, thereby decreasing $PAO_2$ slightly more than would be expected from the dilution of $PACO_2$. To account for changes in R, a useful form of the alveolar air equation for clinical purposes is

$$PAO_2 = PIO_2 - \frac{PACO_2}{R}$$

When $\text{PACO}_2$ is 40 and R is 0.8, $\text{PAO}_2$ is 100 mm Hg. Note that breathing 40% oxygen raises $\text{PAO}_2$ to 235 mm Hg because $\text{FIO}_2$ is now 0.40. Note that this equation is less accurate during oxygen breathing when more arduous forms of the alveolar air equation may be used. However, this inaccuracy is seldom of importance in the clinical setting.

Because the partial pressures of alveolar gases must always equal the same total pressure, any increase in one must be associated with a decrease in the other. For example, if $\text{PaCO}_2$ is 80 mm Hg and the patient is breathing room air (assuming an R of 0.8), the highest that $\text{PAO}_2$ can be is 50 mm Hg.

# Diffusion

## Principles

According to Henry's law of diffusion, the diffusion rate for gases in a liquid phase is directly proportional to their solubility coefficients. For example, in water,

$$\frac{solubility\ of\ CO_2}{solubility\ of\ O_2} = \frac{0.592}{0.0244} = \frac{24.3}{1}$$

Therefore, carbon dioxide diffuses more than 24 times as fast as oxygen. The diffusion rate of a gas in the gas phase is inversely proportional to the square root of molecular weight (Graham's law). Therefore, in the gas phase,

$$\frac{rate\ for\ CO_2}{rate\ for\ O_2} = 0.85$$

That is, carbon dioxide diffuses slower in the gas phase than does oxygen. Combining Henry's and Graham's laws for a system with both a gas phase and a liquid phase (e.g., alveolus and blood): carbon dioxide diffuses 24.3 × 0.85 = 20.7 times as fast as oxygen.

The barriers through which a gas must travel when diffusing from an alveolus to the blood include the alveolar epithelial lining, basement membrane, capillary endothelial lining, plasma, and red blood cell. As observed on electron micrographs of lung tissue, the thinnest part of the barrier is 0.2 µm but may be as much as 3 times this thickness.

Fick's law of diffusion, modified for gases, states:

$$Q/\text{min} = \frac{KS(P_1 - P_2)}{d}$$

The amount of gas (Q) diffusing through a membrane is directly proportional to the surface area available for diffusion (S), the pressure difference of the two gases on either side of the membrane, and a constant (K) that depends on the solubility coefficient of the gas and the characteristics of the particular membrane and liquid used and is inversely proportional to the distance (d) through which the gas has to diffuse. In the lung of a given subject, exact values for K, *S*, and *d* are unknown. Therefore, for the lung, Bohr and Krogh suggested “diffusing capacity” (DL). DL is simply the inverse of the total resistance to diffusion and can be expressed as the sum of the individual component resistances:

$$\frac{1}{DL} = \frac{1}{DM} + \frac{1}{\theta Vc}$$

where 1/DM is the resistance to diffusion of the gas across the alveolar-capillary membrane, plasma, and red blood cell membrane; θ is the reaction rate of the gas with hemoglobin (Hb); and *Vc* is the pulmonary capillary blood volume.

## Measurement

Carbon monoxide and oxygen have been used to measure DL. Although the diffusing capacity of the lung for oxygen (DLO$_2$) has been measured, the process is both complicated and fraught with technical problems because the average capillary oxygen tension must be determined. For this reason, and because a defect in DLO$_2$ is rarely the cause of hypoxemia, it is not used in the clinical setting. CO, however, has been used extensively in children to test diffusing capacity. The advantage of using CO is its remarkable affinity for Hb, some 210 times that of oxygen; therefore, the capillary PCO is negligible and offers no backpressure for diffusion. To calculate the diffusing capacity of the lungs for CO (DLCO) one need know only the amount of CO taken up per unit time and the PACO.

Many techniques have been developed to measure the DLCO, but only two are discussed in this chapter. The measurement of steady-state DLCO is performed by having the patient breathe a gas mixture containing 0.1% CO for several minutes. Although this measurement requires only a little patient cooperation, its disadvantage is that the value obtained is strongly influenced by maldistribution of the inspired air; if the inhaled gas mixture is not distributed properly to all parts of the lung, the measured DLCO will be decreased but not because of changes in DM, $\theta$, or Vc.

The second technique, the measurement of single-breath DLCO, is less affected by airway disease. In this test, the subject takes a single large breath (from RV to TLC) of a CO-containing gas mixture. Following a 10-second breath-hold, the expired gases are collected so that PACO can be determined.

The difference between these two techniques is exemplified by the patient with acute asthma, in whom the steady-state DLCO value will be decreased, whereas the single-breath DLCO value will be normal or increased. Another advantage of the single-breath DLCO method results from the inclusion of helium in the inspired gas. This inert gas allows the DLCO to be corrected for the alveolar volume (VA) in which it was distributed, a measurement known as KCO:

$$\mathrm{K_{CO}} = \frac{\mathrm{D_{LCO}}\ \text{single breath}}{\text{alveolar volume}}$$

The KCO reflects the physiology of the lung[65] and is the most useful parameter for comparing the DL of children of different ages and hence different lung volumes. In addition, the KCO helps differentiate among simple loss of lung units (atelectasis), a decrease in pulmonary blood volume (emphysema), and the (albeit rarely seen) true diffusion defect.

The DLCO increases throughout childhood, is related to lung growth, and correlates best with subject height or body surface area. Clinically, a reduction in DLCO may occur for many reasons, including surgical lung resection, diffuse lung disease (pulmonary fibrosis, cystic fibrosis), and emphysematous destruction of the alveolar-capillary membrane. In addition, anemia may decrease the DLCO, and equations to correct the DLCO for anemia are available. Increases in DLCO rarely occur and usually result from pulmonary vascular engorgement (increased Vc) or pulmonary hemorrhage (e.g., Goodpasture syndrome and idiopathic pulmonary hemosiderosis).

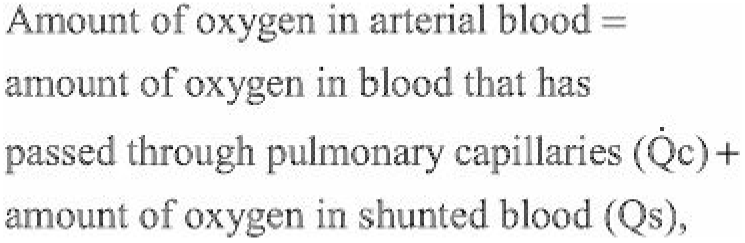
It is important to note that with a nonexercising patient, impaired diffusion of oxygen from the alveolar air to the pulmonary capillary is rarely the cause of a low $PaO_2$. Diffusion limitation may occur during exercise in patients with interstitial lung disease or in healthy individuals performing extreme exercise. Hypoxemia in pulmonary diseases usually results from alveolar hypoventilation or an imbalance between ventilation and perfusion of lung units. Thus, low DLCO values almost always reflect abnormalities in gas exchange rather than true diffusion defects.

## Shunt and Ventilation-Perfusion Relationships

There are four pulmonary causes of arterial hypoxemia. We have already discussed two of these, alveolar hypoventilation and diffusion defects. The remaining two, intrapulmonary shunt and ventilation-perfusion defects, result from abnormalities in the distribution of the ventilation and perfusion of the gas-exchanging units.

*Shunt* refers to blood that reaches the systemic circulation without coming in direct contact with a ventilated area of the lung. Because this blood is deoxygenated, it lowers the $PaO_2$. There are several causes of shunt. In normal lungs, a small amount of shunt is present because the Thebesian veins and a portion of the bronchial vascular flow drain into the left side of the heart. Pathologic shunts result when abnormal vascular channels exist, as in cyanotic congenital heart disease or pulmonary arteriovenous fistula. Shunt, however, most commonly occurs in diseased lungs because alveoli are not ventilated but are still being perfused. This condition, known as intrapulmonary shunting, occurs in a variety of lung diseases, including pulmonary edema, atelectasis, and pneumonia.

A characteristic feature of shunt is that the resultant hypoxemia cannot be corrected by breathing pure oxygen, a reasonable consequence because, by definition, shunted blood does not pass ventilated lung units. One caveat is that when patients are placed on high oxygen concentrations, a very small increase in $PaO_2$ may occur because the blood-perfusing ventilated units will depart those units with higher amounts of dissolved oxygen. The characteristic that shunt is very poorly responsive to breathing pure oxygen can be a useful clinical tool; if $PaO_2$ is less than 500 mm Hg while the subject is breathing 100% oxygen, a significant shunt is present. If mixed venous (pulmonary arterial) blood is available for measurement (or a mixed venous oxygen concentration is assumed), the amount of shunt can be calculated at any inspired oxygen concentration using the shunt equation:



Amount of oxygen in arterial blood =
amount of oxygen in blood that has
passed through pulmonary capillaries ($\dot{Q}c$) +
amount of oxygen in shunted blood (Qs),

and

Amount of oxygen = content of oxygen per liter ($Co_2$)
× blood flow ($\dot{Q}$).

Therefore,

$$Cao_2\,\dot{Q}t = Cco_2\,\dot{Q}c + C\bar{v}o_2\,\dot{Q}s$$

where $\dot{Q}$ is total blood flow. Since $\dot{Q}c = \dot{Q}t - \dot{Q}s$,

$$Cao_2\,\dot{Q}t = Cco_2\,\dot{Q}t - Cco_2 + \dot{Q}s + C\bar{v}o_2\,\dot{Q}s$$

and

$$\frac{\dot{Q}s}{\dot{Q}t} = \frac{Cco_2 - CaO_2}{Cco_2 - C\bar{v}O_2}$$

where $\dot{Q}s/\dot{Q}t$ is the fraction of the total cardiac output that is shunted.

The average ratio between alveolar ventilation and blood flow (VA/Q) is 0.8, but the ratio even in the normal lung may range from near zero (not ventilated) to infinity (not perfused). Nevertheless, the most common cause of arterial hypoxemia is a result of mismatch of ventilation and perfusion within the lung, which increases the normal scatter of VA/Q values around the mean value. When a lung unit receives inadequate ventilation relative to its blood flow, $P_{ACO_2}$ rises (toward the mixed venous value of 46 mm Hg) and $P_{AO_2}$ falls (toward the mixed venous value of about 40 mm Hg) and the oxygen content of the end-capillary blood falls. When this blood mixes with blood coming from normal VA/Q regions of the lung, the result is a lowering of oxygen concentration and arterial hypoxemia (so-called *shunt-like effect*). In contrast to what occurs in a true shunt, administration of an enriched oxygen mixture will correct the hypoxemia due to ventilation-perfusion mismatch by raising $P_{AO_2}$ ($P_{N_2}$ must decrease to keep the sum of the partial pressures of gases equal to $P_B$). The increased $P_{AO_2}$ results in an increased concentration of oxygen in the pulmonary capillary blood.

Whatever the absolute amount of regional ventilation and perfusion, the lung has intrinsic regularity mechanisms that are directed toward the preservation of normal $\dot{V}A/\dot{Q}$ ratios. When $\dot{V}A/\dot{Q}$ is high, the low carbon dioxide concentration results in local constriction of airways and tends to reduce the amount of ventilation to the area. When $\dot{V}A/\dot{Q}$ is low, the high alveolar carbon dioxide concentration results in local airway dilation and tends to increase ventilation to the area. Furthermore, a low $\dot{V}A/\dot{Q}$ with an associated low alveolar oxygen concentration causes regional pulmonary vasoconstriction and produces a redistribution of blood flow to healthier lung units. These effects on airways and vessels from changing gas tensions tend to preserve a normal $\dot{V}A/\dot{Q}$, but they are limited mechanisms, and derangements are common with pulmonary disease.

# Systemic Gas Transport

## Oxygen Transport

Once oxygen molecules have passed from the alveolus into the pulmonary capillary, they are transported in the blood in two ways. A small proportion of the oxygen exists as dissolved oxygen in the plasma and water of the red blood cell. For 100 mL of whole blood equilibrated with a $PO_2$ of 100 mm Hg, 0.3 mL of oxygen is present as dissolved oxygen. If this represented the total oxygen-carrying capacity of blood, cardiac output would have to be greater than 80 L/min to allow 250 mL of oxygen to be consumed per minute. During 100% oxygen breathing, $PaO_2$ is approximately 650 mm Hg, and 100 mL of blood contains 2.0 mL of dissolved oxygen; a cardiac output of about 12 L/min would be required if no Hb were present and if the tissues could extract all of the oxygen.

Because 1 g of Hb can combine with 1.39 mL of oxygen, between 40 and 70 times more oxygen is carried by Hb than by the plasma, enabling the body to achieve a cardiac output at rest of 5.5 L/min with an oxygen uptake of 250 mL/min.

The potential usefulness of hyperbaric oxygen (i.e., oxygen under very high pressures) for a variety of clinical conditions is because at a pressure of 3 atmospheres (absolute) ($PAO_2$ of about 1950 mm Hg), approximately 6.0 mL of oxygen is dissolved in 100 mL of whole blood, and this amount can meet the metabolic demands of the tissues under resting conditions even when no Hb is present.

The remarkable oxygen-carrying properties of blood depend not on the solubility of oxygen in plasma but on the unusual properties of Hb. Fig. 6.25 illustrates the oxyhemoglobin dissociation curve, showing that Hb is nearly 95% saturated at a $PO_2$ of 80 mm Hg. The steep portion of the curve, up to about 50 mm Hg, permits large amounts of oxygen to be released from Hb with small changes in $PO_2$. Under normal circumstances, 100% oxygen breathing will raise the amount of oxygen carried by the blood by only a small amount, because at a $PO_2$ of 100 mm Hg, Hb is already 97.5% saturated. Even with air breathing, one is on the flat portion of the curve. The presence of a right-to-left shunt markedly affects $PO_2$ but may reduce the percentage saturation only minimally. For example, a 50% shunt with venous blood containing 15 mL of oxygen/100 mL will reduce the oxygen content of 100 mL of blood only from 20 mL to 17.5 mL. The blood is still 88% saturated, but $PaO_2$ is now 60 mm Hg instead of 100 mm Hg. Thus, the change in oxygen content is linearly related to the amount of right-to-left shunt, but the change in $PO_2$ is not, because the oxyhemoglobin dissociation curve is S shaped. It is also apparent that at levels greater than 60 mm Hg, $PaO_2$ is a more sensitive measure of blood oxygenation, because neither percentage saturation nor oxygen content changes as much as $PO_2$ in this range. However, at $PO_2$ below about 60 mm Hg, relatively small changes of $PO_2$ produce large changes in saturation and content, and in this range, the measurement of content may be more reliable than the measurement of $PO_2$.

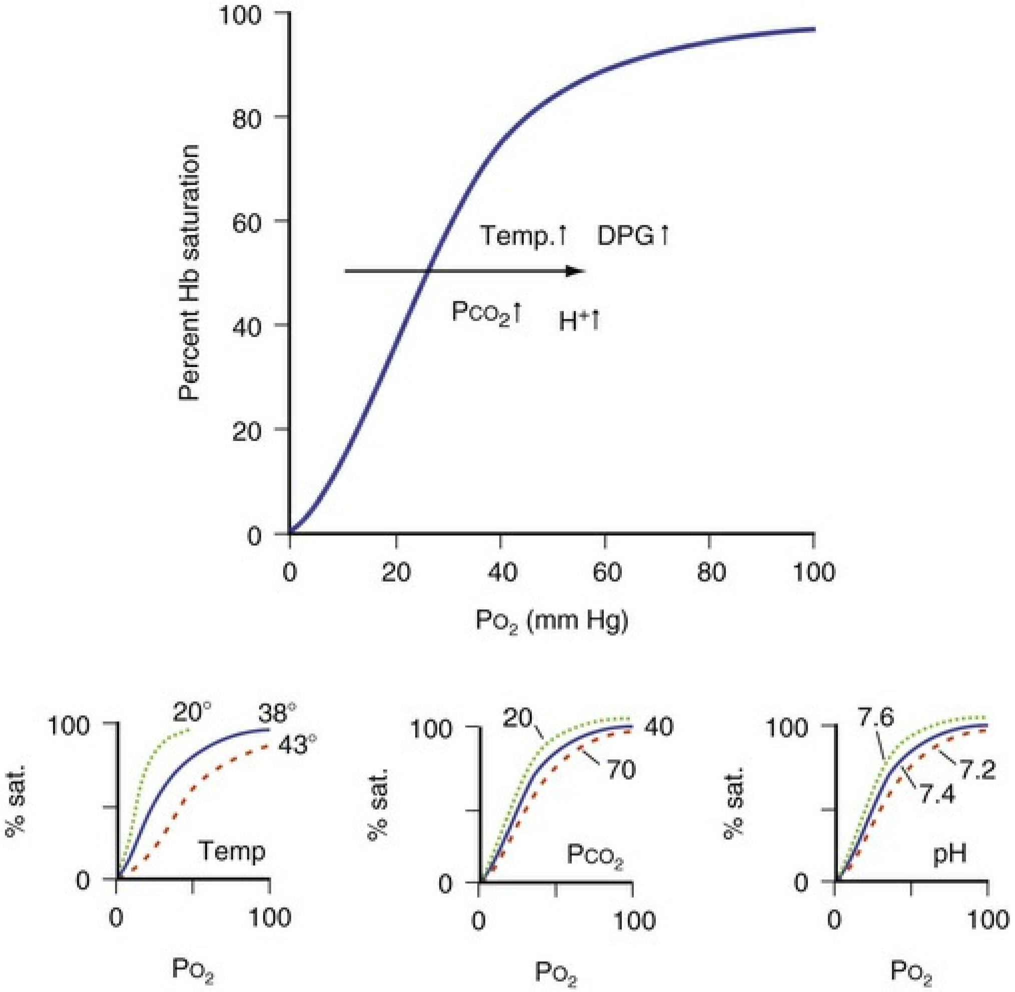


**FIG. 6.25** Oxyhemoglobin dissociation curves. The large graph shows a single dissociation curve, applicable when the pH of the blood is 7.40 and temperature is 38°C. The blood oxygen tension and saturation of patients with carbon dioxide retention, acidosis, alkalosis, fever, or hypothermia will not fit this curve because it shifts to the right or left when temperature, pH, or $P\text{CO}_2$ is changed. Effects on the oxyhemoglobin dissociation curve of change in temperature *(upper left)* and in $P\text{CO}_2$ and pH *(lower right)* are shown in the smaller graphs. A small change in blood pH occurs regularly in the body (i.e., when mixed venous blood passes through the pulmonary capillaries, $P\text{CO}_2$ decreases from 46 to 40 mm Hg, and pH increases from 7.37 to 7.40). During this time, blood changes from a pH of 7.37 dissociation curve to a pH of 7.40 dissociation curve. Note that increased 2,3-diphosphoglycerate also shifts the curve to the right. (From West JB. *Respiratory Physiology—The Essentials,* 5th ed. Baltimore: Lippincott Williams & Wilkins, 1995.)

The oxyhemoglobin dissociation curve is affected by changes in pH, $P_{CO_2}$, and temperature. A decrease in pH, an increase in $P_{CO_2}$ (Bohr effect), or an increase in temperature shifts the curve to the right, particularly in the 20 to 50 mm Hg range. Thus, for a given $P_{O_2}$, the saturation percentage is less under acidotic or hyperpyrexic conditions. In the tissues, carbon dioxide is added to the blood, and this facilitates the removal of oxygen from the red blood cells. In the pulmonary capillaries, carbon dioxide diffuses out of the blood, facilitating oxygen uptake by Hb. An increase in temperature has an effect similar to that of an increase in $P_{CO_2}$ and thus facilitates oxygen removal from the blood by the tissues. Note that a patient who is pyrexic with carbon dioxide retention could not have a normal oxygen saturation during air breathing because of the Bohr and temperature effects on the oxyhemoglobin dissociation curve.

The erythrocyte concentration of 2,3-diphosphoglycerate (DPG) plays a major role in shifting oxyhemoglobin dissociation curves. DPG and Hb are present in about equimolar concentrations in adult human red blood cells. There is strong binding between DPG and the β chain of Hb, and this complex is highly resistant to oxygenation. Shifts of the dissociation curve to the right associated with an increased DPG concentration (e.g., in anemia) facilitate the release of oxygen to the tissues. Because erythrocyte DPG concentration can change within a matter of hours, a regulatory role for DPG in maintaining optimal tissue oxygenation has been suggested.

The fetal oxyhemoglobin dissociation curve is to the left of the adult curve at a similar pH. Thus, at a given $P_{O_2}$, fetal Hb contains more oxygen than adult Hb. This property ensures that an adequate amount of oxygen will reach fetal tissues, since the fetus *in utero* has a $Pa_{O_2}$ of about 20 to 25 mm Hg in the descending aorta. The different affinity of fetal Hb for oxygen results from its interaction with DPG. Both fetal and adult red blood cells have similar intracellular concentrations of DPG, but fetal Hb, which has a $\gamma$ chain instead of a β chain, interacts less strongly with this molecule; therefore, the fetal oxyhemoglobin curve is to the left of the adult curve. Fetal Hb disappears from the circulation shortly after birth, and less than 2% is present by a few months of age. Normal fetal development is not dependent on differences in maternal and fetal Hbs, because they are identical in some species.

Abnormal Hbs differ in their oxygen-carrying capacity. For example, Hb M is oxidized by oxygen to methemoglobin, which does not release oxygen to the tissues; a large amount is incompatible with life. The formation of methemoglobin by agents such as nitrates, aniline, sulfonamides, acetanilid, phenylhydrazine, and primaquine may also be life threatening. Congenital deficiency of the enzyme Hb reductase is also associated with large amounts of methemoglobin, and affected patients are cyanotic in room air. Similarly, sulfhemoglobin is unable to transport oxygen. CO has 210 times more affinity for Hb than oxygen, so it is important to note that $PO_2$ may be normal in CO poisoning but oxygen content will be reduced markedly.

Thus, a variety of factors may affect the position of the oxyhemoglobin dissociation curve. The position of the curve may be described by measuring the $PO_2$ at which there is 50% saturation, the so-called $P_{50}$. When the curve is shifted to the left, the $P_{50}$ is low; when the curve is shifted to the right, the $P_{50}$ is elevated. Although the $P_{50}$ is the traditional method of describing the affinity of Hb for oxygen (see Fig. 6.25), a more appropriate clinical measurement is the $P_{90}$. This is the $PaO_2$ at which the Hb is 90% saturated and, as outlined in the following section, corresponds to the goal of oxygen therapy (Table 6.3).

**Table 6.3**

**Effect of Temperature and Acute Respiratory Acidosis and Alkalosis on Hemoglobin Oxygen Affinity**

| Temperature[a] (°C) | $P_{50}$ | $P_{90}$ |
|---|---|---|
| 28 | 16.5 | 35 |
| 32 | 20.5 | 44 |
| 40 | 32.0 | 68 |

| RESPIRATORY ACIDOSIS AND ALKALOSIS[b] | | | |
|---|---|---|---|
| pH | $PCO_2$ | $P_{50}$ | $P_{90}$ |
| 7.56 | 20 | 22 | 48 |
| 7.48 | 30 | 24.5 | 52.5 |
| 7.40 | 40 | 27 | 58 |

|  |  |  |  |
|---|---|---|---|
| 7.32 | 50 | 29.5 | 63 |
| 7.26 | 60 | 31 | 67$P_{50}$ and $P_{90}$: $PO_2$ at which 50% or 90% of the hemoglobin is saturated. |

[a]$PCO_2$ = 40 mm Hg, pH = 7.40.

[b]Temperature = 37°C.

## Assessment of Blood Oxygenation

It is challenging to assess oxygenation at the bedside because the degree of visible cyanosis is influenced by many factors, including the patient's Hb concentration and integrity of peripheral perfusion. Clinical cyanosis reflects the absolute concentration of deoxyhemoglobin (Hb), not the ratio of Hb to oxyhemoglobin ($HbO_2$). Thus, the presence of anemia makes the clinical detection of a low $PaO_2$ more difficult, whereas cyanosis may be present in polycythemic patients even though the $PaO_2$ is only minimally decreased. It has been estimated that cyanosis will be seen when there is approximately 5 gm/dL of reduced Hb in the capillaries, which correlates with approximately 3 gm/dL in the arterial blood.[66]

$HbO_2$ can be assessed using oximeters. The pulse oximeter is most commonly used to noninvasively assess a patient's blood oxygenation. The pulse oximeter passes two different wavelengths of light, 660 nm and 940 nm, through the patient's tissues. $HbO_2$ absorbs the 660-nm wavelength, whereas Hb absorbs the 940-nm wavelength; the oximeter then determines the ratio of $HbO_2/(HbO_2 + Hb)$. The measurement is timed with the pulse of arterial blood and thus facilitates the measurement of an arterial-like Hb saturation value. Although appropriate in the majority of situations, it is important to remember the limitations of a pulse oximeter. It neither detects carboxyhemoglobin (HbCO) nor methemoglobin (metHb), and it will not work well if there is decreased perfusion or the patient has a dyshemoglobinemia. Technical issues, such as skin pigmentation, nail polish or motion artifacts, can also compromise the measurement. The Hb oxygen saturation of a blood sample can be directly analyzed using a co-oximeter, a device that uses multiple wavelengths of light to distinguish $HbO_2$ from Hb, HbCO, and metHb. The use of a co-oximeter is mandatory when the clinician suspects CO poisoning, as HbCO is pink, or if metHb is suspected.

The $PaO_2$ of blood can be directly measured using the Clark oxygen electrode within a blood gas analyzer. Usually, the Hb saturation of a blood gas sample is calculated from the $PaO_2$ using assumptions for various parameters, such as the p50 of the patient's Hb, with correction for the patient's core body temperature.

Normal values for $HbO_2$ during infancy, as measured by pulse oximetry, and $PaO_2$ from arterial blood samples, are illustrated in Fig. 6.26.

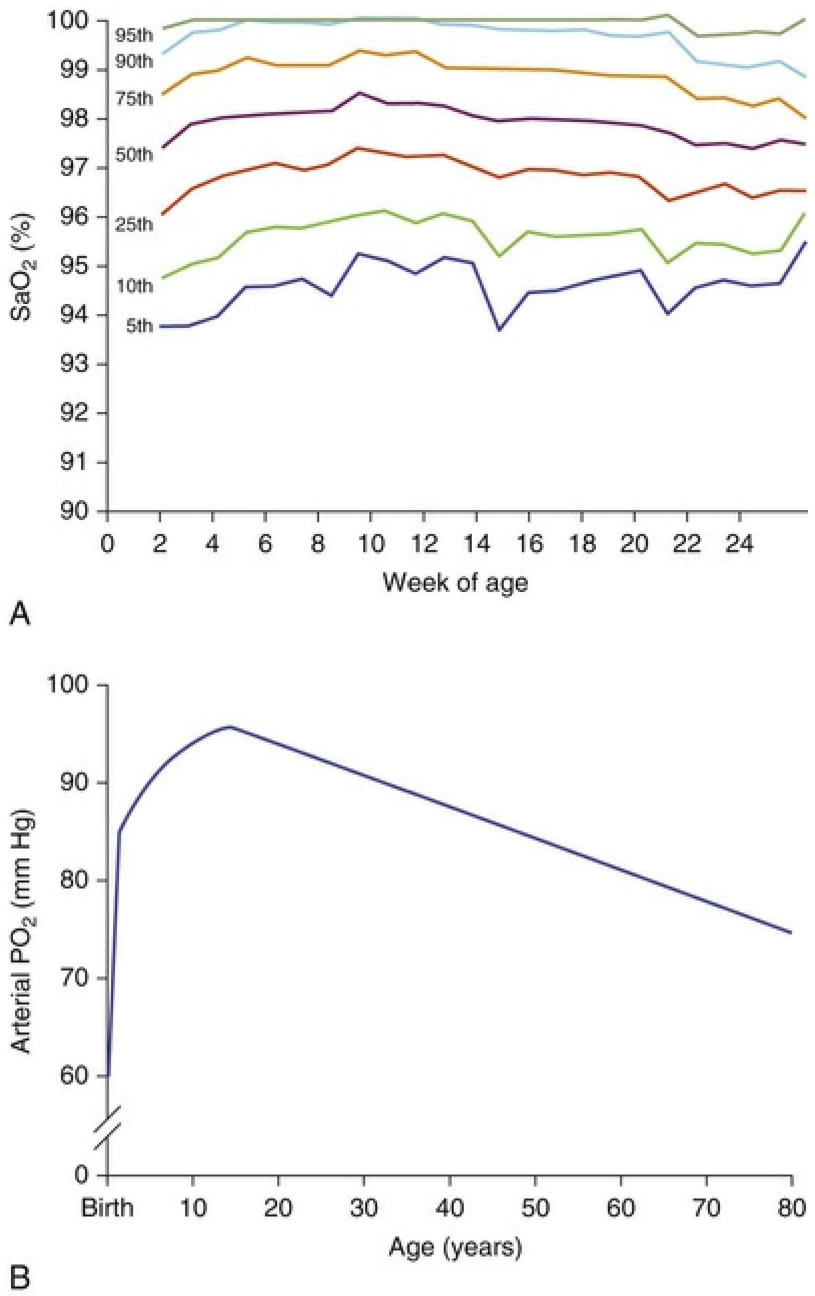

**FIG. 6.26** (A) Median baseline $Sa\text{O}_2$ ($Sp\text{O}_2$) for healthy term infants who were studied at each postanatal week from 2 to 25 weeks after birth. Variations in $Sp\text{O}_2$ with increasing age were not significant. (B) Arterial $P\text{O}_2$ as a function of age from infancy to 80 years of age. The figure represents the data from numerous studies. (Median baseline $Sa\text{O}_2$ reproduced with permission from Hunt CE, Corwin MJ, Lister G, et al. Longitudinal assessment of hemoglobin oxygen saturation in healthy infants during the first 6 months of age. Collaborative Home Infant Monitoring Evaluation (CHIME) Study Group. *J Pediatr.* 1999;135:580-586; Arterial $P\text{O}_2$ reproduced with permission from Murray JF. *The Normal Lung: A Basis for the Diagnosis and Treatment of Pulmonary Disease*, 2nd ed. Philadelphia: Saunders; 1986.)

Today the usual clinical practice is to measure $SaO_2$ with a pulse oximeter and to estimate $PaCO_2$ by measuring the $PCO_2$ of either a peripheral venous blood or arteriolized blood sample. The latter refers to a blood sample that was obtained after the extremity was warmed and received topical medications to increase capillary blood flow and bring the sample's characteristics closer to those of arteriolar blood. In individuals who have adequate peripheral perfusion, it can be assumed that the $PaCO_2$ will be 6 mm Hg or less than the peripheral venous $CO_2$ gas tension ($PvCO_2$). If the estimated $PaCO_2$ is normal, or less than normal, then the clinician can be confident that the patient is not in hypercarbic respiratory failure. However, if the estimated $PaCO_2$ is elevated, then the clinician must obtain an arterial sample to directly measure the $PaCO_2$ because an elevated $PCO_2$ in an arteriolized capillary or venous sample may indicate decreased peripheral perfusion. The $PO_2$ and calculated $SaO_2$ from a venous blood gas should be ignored.

## Oxygen Delivery to Tissues

The cardiopulmonary unit not only must oxygenate the blood but also must transport oxygen to the systemic tissues in adequate amounts. The total oxygen delivery to the systemic tissues is determined by the $PaO_2$, the amount of saturated Hb, and the left ventricular output (see the equation that follows). For an average adult with a $PaO_2$ of 100 mm Hg, a Hb concentration of 15 g/100 mL (97.5% saturation), and a cardiac output (C.O.) of 5 L/min, approximately 1000 mL of oxygen is delivered to systemic tissues each minute. This large delivery of oxygen provides a significant margin of safety because, under normal circumstances, the systemic tissues use only one fourth of the available oxygen; mixed venous $PO_2$ is 40 mm Hg, and Hb is 73% saturated. Mixed venous blood is by definition the blood within the main pulmonary artery but is often estimated from a central venous line.

The systemic oxygen transport equation is useful to emphasize a therapeutic principle: the three practical ways to improve oxygenation of peripheral tissues are to increase Hb saturation, to increase Hb concentration, and to augment cardiac output.

$$\text{oxygen delivery} = \text{blood oxygen content} \times \text{cardiac output},$$

where

$$\begin{aligned}&\text{blood oxygen content}/100\ \text{mL} = \\ &\quad \text{dissolved oxygen } (0.003\ \text{mL}/100\ \text{mL blood} \times \\ &\quad \text{PaO}_2) + \text{oxygen carried by hemoglobin} \\ &\quad (1.39\ \text{mL/g} \times \text{gHb}/100\ \text{mL})\end{aligned}$$

# Oxygen Therapy

## Increased Inspired Mixtures

The concentration of oxygen in the inspired air should be increased when tissue oxygenation is inadequate. The response to an increased inspired oxygen concentration depends on which cause of hypoxia is present (Box 6.1). Most of the conditions characterized by hypoxemia respond well to added oxygen. For example, if airway disease results in a 30% decrease in ventilation to an acinus, this can be corrected by an appropriate increase in the concentration of oxygen in the inspired gas. In contrast, patients with shunts will only respond to a minimal degree because the shunted blood does not perfuse alveoli. The slight improvement in $PaO_2$ and $SaO_2$ that may be seen when patients with extensive intrapulmonary shunting inhale high concentrations of oxygen results from the additional amount of dissolved oxygen in the blood that perfuses ventilated alveoli. A direct attack on the underlying disorder in anemia, ischemia, and poisonings is clearly indicated; oxygen therapy may be a life-saving measure during the time required to treat the disease.

**Box 6.1**

## Four Types of Hypoxia and Some Causes

### Hypoxemia (Low $P_{O_2}$ and Low Oxygen Content)

Deficiency of oxygen in the atmosphere
Hypoventilation
Uneven distribution of alveolar gas and/or pulmonary blood flow
Diffusion impairment
Venous-to-arterial shunt

### Deficient Hemoglobin (Normal $P_{O_2}$ and Low Oxygen Content)

Anemia
Carbon monoxide poisoning

### Ischemic Hypoxia (Normal $P_{O_2}$ and Normal Oxygen Content)

General or localized circulatory insufficiency
Tissue edema
Abnormal tissue demands

### Histotoxic Anoxia (Normal $P_{O_2}$ and Normal Oxygen Content)

Poisoning of cellular enzymes so that they cannot use the available oxygen (e.g., cyanide poisoning)

Oxygen therapy can be utilized to facilitate the removal of other gases loculated in body spaces, such as air in pneumothorax, pneumomediastinum, and ileus. High inspired oxygen mixtures effectively wash out body stores of nitrogen. With air breathing, the blood that perfuses the tissue spaces has an arterial oxygen tension of 100 mm Hg and a venous oxygen tension of 40 mm Hg. With oxygen breathing, although arterial tensions increase to 600 mm Hg, venous oxygen tensions do not increase above 50 to 60 mm Hg because of oxygen consumption and the shape of the dissociation curve. With air breathing, arterial and venous nitrogen tensions are the same, about 570 mm Hg. If the loculated gas were air at atmospheric pressure, the gradient for the movement of nitrogen to the blood would be very small. After nitrogen washout, with oxygen breathing, the lack of high elevation in venous oxygen tension permits movement of both nitrogen and oxygen from the pneumothorax into the blood. The increased pressure differences increase the rate of absorption of loculated air some 5- to 10-fold. This augmented clearance occurs while the extrapulmonary gas is predominately nitrogen.

## Administration of Oxygen

There are several methods of delivering enriched oxygen gas mixtures to nonintubated patients. Known concentrations of oxygen can be piped into chambers that surround the infant's head, such as an oxygen tent or a head box. Usually, these chambers allow significant leakage of gases, so it is imperative that the $O_2$ concentration be measured inside the chamber near the patient's face. Another method is to run pure oxygen through nasal prongs or cannulae at specified flow rates. Although this method can be efficacious in improving the $PaO_2$, one must remember that it does not provide a constant $FIO_2$ during the breath, nor can the $FIO_2$ be accurately calculated or measured. The reason is that patients will “beat the system,” because their inspiratory flow rates exceed the rate at which the pure oxygen is being piped toward their faces. A simple calculation illustrates the point. If a 70-kg man breathes at 30 breaths/min with an inspiratory/expiratory time ratio of 1 : 1, his duration of inspiration will be 1 second. Given a tidal volume of 0.5 L, his average inspiratory flow rate will be 0.5 L/sec or 30 L/min. Given that nasal prongs are usually set at 2 to 6 L/min for the average 70-kg man, it is immediately obvious that his initial portion of inspiration will be 100% oxygen but that the percentage will decrease quickly toward that of room air by the end of inspiration. This pattern is applicable not only to adults but also to younger children. Recently, some intensive care units have been administering very high oxygen flow rates via nasal cannulae to infants and young children; this not only increases the inspired oxygen concentration, but also increases the mean airway pressure.

Thus, although one can "guesstimate" what flow rate of oxygen the patient will require to normalize the blood oxygen tension, the actual $FIO_2$ will vary within and between breaths, especially if the patient changes the depth or pattern of breathing. In practice today in hospitalized children, oxygen flow rate is titrated by measurement of pulse oximetry.

## Hazards of High Oxygen Mixtures

Hypoxemia in conditions associated with alveolar hypoventilation, such as chronic pulmonary disease and status asthmaticus, may be overcome by enriched oxygen mixtures without concomitant lessening of the hypercapnia. The patient may appear pink but become narcotized under the influence of carbon dioxide retention. In chronic respiratory acidosis, respiration may be maintained chiefly by the hypoxic drive. This is a condition that is rarely seen in pediatric patients but may occur in the terminally ill patient with cystic fibrosis.

With the institution of oxygen therapy, there is usually a small drop in minute ventilation as the hypoxic stimulus to breath is removed by the increase in $PaO_2$. Very rarely, a patient with chronic hypercarbic respiratory failure may cease breathing if excessive oxygen is given. It is therefore essential to measure the pH and $PaCO_2$ in addition to the $PaO_2$ or saturation in these groups of patients. The goal of oxygen therapy is to give just enough oxygen to return the arterial oxygen saturation to the appropriate amount for the patient. The usual target is 90% in the infant, child, and adult. However, the target saturation may be less in the premature infant who is susceptible to retinopathy of prematurity or higher when there is significant pulmonary hypertension. When there is increased intracranial pressure, the clinician should utilize arterial blood samples to maintain the $PaO_2$ well above 100 mm Hg to ensure full saturation of Hb and to further increase the oxygen content of blood by augmenting the amount of dissolved oxygen.

Excessive oxygenation of the blood can be dangerous. Human volunteers in pure oxygen at 1 atmosphere experience symptoms in about 24 hours, chiefly substernal pain, and paresthesias. Laboratory animals exposed for longer periods die of pulmonary congestion and edema in 4 to 7 days. The toxicity of oxygen is directly proportional to its partial pressure. Symptoms occur within minutes under hyperbaric conditions and yet are not present after 1 month in pure oxygen at 1/3 atmosphere. Some of the acute effects of oxygen are a slight decrease of minute ventilation and cardiac output and constriction of retinal and cerebral vessels and the ductus arteriosus. Retinal vasoconstriction does not seem to be a significant problem in mature retinas that are fully vascularized. In premature infants, however, the vasoconstriction may lead to ischemia. After the cessation of oxygen therapy, or with maturation of the infant, neovascularization of the retina occurs. The disorderly growth and scarring may cause retinal detachments and fibroplasia, which appears behind the lens; hence, the names retrolental fibroplasia and retinopathy of prematurity.

As the care of premature infants with acute lung disease has improved, the survival rate has increased impressively. Regrettably, many of the survivors have chronic lung disease of prematurity or bronchopulmonary dysplasia (see Chapter 20). At the present time, it is difficult to determine the relative contributions of prematurity, ventilator-induced barotrauma, oxygen toxicity, and the preceding acute lung injury in the evolution of this serious disorder. It does seem prudent, however, to minimize the $FIO_2$ in these patients, given the damage that occurs in totally normal lungs exposed to very high concentrations of oxygen.

## Carbon Dioxide Transport and Acid-Base Balance

### Buffering and Transport

Acids are normally produced in the body at the rates of 15 to 20 moles of carbonic acid and 80 mmol of fixed acids per day. For the cells to maintain their normal metabolic activity, the pH of the environment of the cells must be close to 7.40. The understanding of the regulation of hydrogen ion concentration requires knowledge of the buffering action of the chemical constituents of the blood and of the role of the lungs and kidneys in the excretion of acids from the body.

The most important constituents for acid-base regulation are the sodium bicarbonate and carbonic acid of the plasma, the potassium bicarbonate and carbonic acid of the cells, and Hb.

The concentration of carbonic acid is determined by the $P_{CO_2}$ and the solubility coefficients of carbon dioxide in plasma and in red blood cell water. Carbonic acid in aqueous solution dissociates as follows:

$$CO_2 + H_2O \leftrightarrow H_2CO_3$$

$$H_2CO_3 \leftrightarrow H + HCO_3^-$$

The law of mass action describes this reaction:

$$\frac{[H^+][HCO_3^-]}{[H_2CO_3]} = K$$

In plasma, K has the value of $10^{-6.1}$. An equivalent form of this equation is

$$pH = pK + \log \frac{[HCO_3^-]}{H_2CO_3}$$

By definition,

$$\mathrm{pH} = -\log[\mathrm{H}^+];\ \mathrm{pK} = -\log \mathrm{K} = 6.1 \text{ for plasma.}$$

Applied to plasma, in which dissolved carbon dioxide exists at a concentration 1000 times that of carbonic acid, the equation becomes

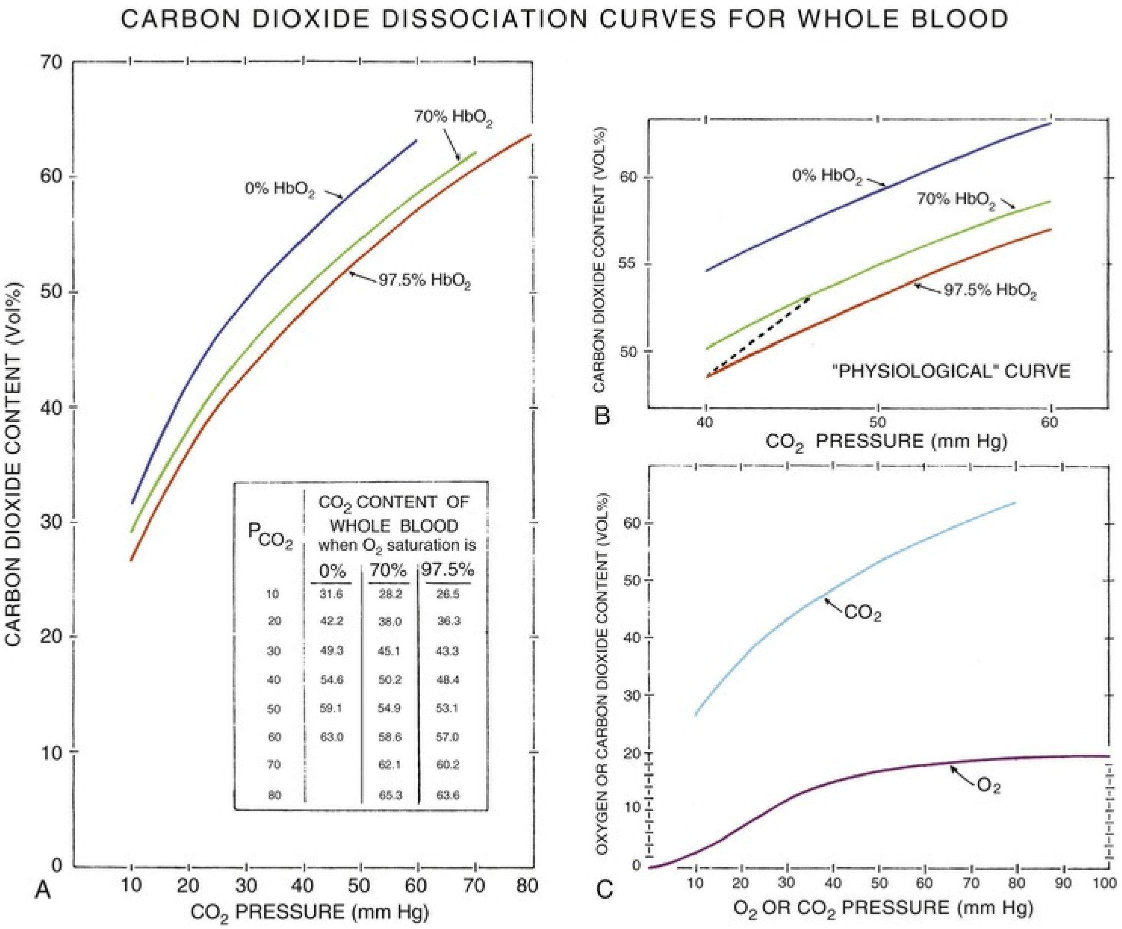
$$pH = 6.1 + \log \frac{[HCO_3^-]}{0.03\ PCO_2}$$

This form of the equation is known as the Henderson-Hasselbalch equation. A clinically useful form of this equation is as follows:

$$H^+(nmol/L) = 24 \times \frac{PCO_2}{HCO_3^-}$$

Thus, at a normal bicarbonate concentration of 24 mEq/L, when $PaO_2$ is 40 mm Hg, hydrogen ion concentration is 40 nM.

Just as oxygen has a highly specialized transport mechanism in the blood to ensure adequate delivery to tissues under physiologic conditions, carbon dioxide produced by the tissues has a special transport system to carry it in the blood to the lung where it is expired. The amount of carbon dioxide in blood is related to the $PCO_2$ in a manner shown in Fig. 6.27. Unlike the relation of oxygen content to $PO_2$, the relation of carbon dioxide content to $PCO_2$ is nearly linear; therefore, doubling alveolar ventilation halves $PaCO_2$. Oxygenated Hb shifts the carbon dioxide dissociation curve to the right (Haldane effect) so that there is a lower carbon dioxide content at a given $PCO_2$. This effect aids in the removal of carbon dioxide from the blood in the lung when venous blood becomes oxygenated. The average arterial carbon dioxide tension ($PaCO_2$) in adults is 40 mm Hg and in infants is closer to 35 mm Hg; venous levels in both are normally 6 mm Hg higher. The small difference between arterial and venous $PCO_2$ is why the effect of venous admixture on arterial $PCO_2$ is very small.

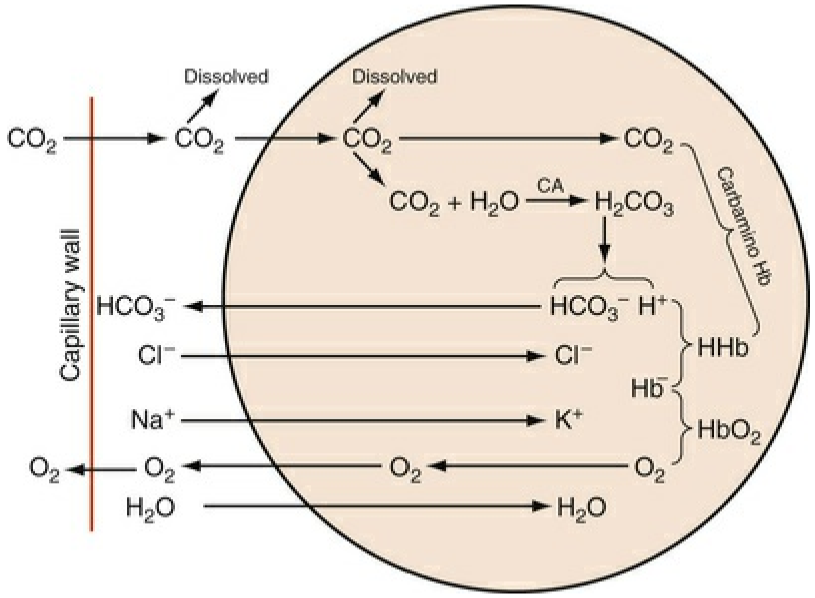


| $P_{CO_2}$ | CO$_2$ CONTENT OF WHOLE BLOOD when O$_2$ saturation is | | |
|---|---|---|---|
| | 0% | 70% | 97.5% |
| 10 | 31.6 | 28.2 | 26.5 |
| 20 | 42.2 | 38.0 | 36.3 |
| 30 | 49.3 | 45.1 | 43.3 |
| 40 | 54.6 | 50.2 | 48.4 |
| 50 | 59.1 | 54.9 | 53.1 |
| 60 | 63.0 | 58.6 | 57.0 |
| 70 | | 62.1 | 60.2 |
| 80 | | 65.3 | 63.6 |

**FIG. 6.27** Carbon dioxide dissociation curve. The large graph (A) shows the relationship between P$CO_2$ and carbon dioxide content of whole blood; this relationship varies with changes in saturation of hemoglobin with oxygen. Thus, P$CO_2$ of the blood influences oxygen saturation (Bohr effect), and oxygen saturation of the blood influences carbon dioxide content (Haldane effect). The oxygen–carbon dioxide diagram gives the correct figure for both carbon dioxide and oxygen at every P$O_2$ and P$CO_2$. (B) Greatly magnified portion of the large graph to show the change that occurs as mixed venous blood (70% oxyhemoglobin, P$CO_2$ 40 mm Hg). *Dashed line* is a hypothetical transition between the two curves. (C) Oxygen and carbon dioxide dissociation curves plotted on same scale to show the important point that the oxygen curve has a steep and a flat portion and that the carbon dioxide curve does not. (From Comroe Jr JH. *The Lung,* 2nd ed. Chicago: Year Book Medical; 1963.)

Carbon dioxide is transported in the blood in three ways:

dissolved in the blood, as bicarbonate, and as carbamino compound. At the tissue level, the processes involved in the uptake of carbon dioxide into the blood are as follows (Fig. 6.28):



Dissolved
Dissolved

$HbO_2$
$O_2$
$O_2$
$H_2O$

**FIG. 6.28** $CO_2$ transport in blood. (See text for further explanation.)

1. Carbon dioxide diffuses into the blood from the tissue. Some carbon dioxide is dissolved in the plasma water in physical solution.
2. Carbon dioxide hydrates slowly in the plasma to form a small amount of carbonic acid.
3. Most of the carbon dioxide enters the red blood cells. A small amount is dissolved in the intracellular water. A fraction combines with Hb to form a carbamino compound.
4. Because of the presence of carbonic anhydrase, a larger fraction in the red blood cell hydrates rapidly to form carbonic acid, which dissociates into $H^+$ plus $HCO_3^-$.
5. Bicarbonate diffuses into plasma because of the concentration gradient, and $Cl^-$ ions enter the cell to restore electrical neutrality.

Hemoglobin is important in the transport of carbon dioxide because of two properties of the molecule. First, it is a good buffer, permitting blood to take up carbon dioxide with only a small change in pH. Second, Hb is a stronger acid when oxygenated than when reduced; thus, when oxyhemoglobin is reduced, more cations are available to neutralize $HCO_3^-$. Carbon dioxide exists in two forms in the red blood cell because of this property of Hb: as bicarbonate ion and as hemoglobin carbamate ($HbNHCOO^-$).

$$KHbO_2 + H_2CO_3 \leftrightarrow HHb + O_2 \uparrow + KHCO_3$$

$$KHbO_2NH_2 + CO_2 \leftrightarrow HHb\dot{c}\ NHCOOK + O_2 \uparrow$$

An enzyme in the red blood cell, carbonic anhydrase, accelerates the reaction $CO_2 + H_2O \leftrightarrow H^+ + HCO_3^-$ some 13,000 times. A concentration gradient between red cell and plasma causes the bicarbonate ion to leave the red cell. Because the red blood cell membrane is relatively impermeable to $Na^+$ and $K^+$, the chloride ion and water move into the red cell to restore electrical neutrality (chloride shift or Hamburger shift). Thus, although the larger portion of the buffering occurs within the red cell, the largest amount of carbon dioxide is in the plasma as $HCO_3^-$ (Table 6.4). The shift of chloride and $HCO_3^-$ was previously thought to be passive, that is, to occur by diffusion due to a concentration gradient. It is now known to be an active process dependent on a specific transport protein within the red blood cell membrane. This anion transport occurs rapidly with a half-time of 50 msec.

## Table 6.4

### Carbon Dioxide in the Blood

| | **Arterial Blood** | | **Venous Blood** | |
|---|---|---|---|---|
| | **M M/L BL** | **%** | **M M/L BL** | **%** |
| Total | 21.9 | | 24.1 | |
| Plasma dissolved | 0.66 | 3 | 0.76 | 3 |
| $CO_2$ | | | | |
| $HCO_3^-$ | 14.00 | 64 | 15.00 | 63 |
| Cells dissolved | 0.44 | 2 | 0.54 | 2 |
| $CO_2$ | | | | |
| $HCO_3^-$ | 5.7 | 26 | 6.1 | 25 |
| $HbNHCOO^-$ | 1.2 | 5 | 1.8 | 7 |

Note: Table gives normal values of various chemical forms of $CO_2$ in blood with an assumed hematocrit level of 46. Approximately twice as much $CO_2$ exists in the plasma as in the red blood cells, chiefly as $HCO_3^-$.

In the lung, a process the reverse of that just described takes place, because carbon dioxide diffuses out of the blood and into the alveoli. Diffusion of $CO_2$ is rapid, so the equilibrium between the $P_{CO_2}$ of the pulmonary capillary and that of alveolar air is promptly achieved. About 30% of the $CO_2$ that is exchanged is given up from hemoglobin carbamate. When Hb is oxygenated in the pulmonary capillary, chloride and water shift out of the red cell, and bicarbonate diffuses in to combine with hydrogen ion to form $H_2CO_3$, which in turn is dehydrated to form carbon dioxide. Carbon dioxide then diffuses out of the cell into the plasma and alveolar gas.

Although red blood cells from newborn infants have less carbonic anhydrase activity than adult cells, no defect in carbon dioxide transport is apparent. However, when breathing 100% oxygen, there is less reduced Hb present in venous blood, and therefore, less buffering capacity for $H^+$ is present, leading to an increased $P_{CO_2}$. This is an important consideration during hyperbaric oxygenation when the venous blood may remain almost completely saturated with oxygen, $H^+$ is less well buffered, and tissue $P_{CO_2}$ rises.

## Acid-Base Balance

To understand acid-base balance within the body, it is important to differentiate between the processes that promote a change in acid–base state and the end result of all these primary and secondary processes. *Acidemia* and *alkalemia* refer to the final acid-base status within the blood (hence the suffix *-emia*). Two processes can promote the development of acidemia: metabolic acidosis (loss of $HCO_3^-$ or gain of $H^+$) and respiratory acidosis (increase in $P_{CO_2}$, which increases $H^+$ via carbonic acid). Two processes can promote the development of alkalemia: metabolic alkalosis (gain of $HCO_3^-$ or loss of $H^+$) and respiratory alkalosis (decrease in $P_{CO_2}$). Obviously, if there is a primary acidotic process, the body will try to maintain homeostasis by promoting a secondary alkalotic process and vice versa. Therefore, to understand the patient's acid-base balance, one must first measure the pH of the blood, and if it is abnormal, determine what primary and secondary (compensatory) processes are involved. This is illustrated in Table 6.5; note, however, that the $HCO_3^-$ shown in Table 6.5 is the standard $HCO_3^-$ (i.e., corrected to a $PCO_2$ of 40 mm Hg; see later section entitled "Difference between Additions of $CO_2$ to Blood *In Vitro* and *In Vivo*").

### Table 6.5

### Blood Measurements in Various Acid-Base Disturbances

| | Standard $CO_2$ (mm Hg) | $PaCO_2$ (mEq/L) | $HCO_3^-$ (mEq/L) | Content pH |
|---|---|---|---|---|
| Metabolic acidosis | ↓ | ↓ | ↓ | ↓ |
| Acute respiratory acidosis | ↓ | ↑ | ↔ | Slight≠ |
| Compensated respiratory acidosis | (↔ or slight ↓) | ≠↑ | ↑≠ | ↑≠ |
| Metabolic alkalosis | ↑≠ | Slight↑ ≠ | ≠↑ | ↑≠ |
| Acute respiratory alkalosis | ≠↑↑ | ↓ | ↔ | Slight ↓ |
| Compensated respiratory alkalosis | (↔ or slight ↑≠) | ↓ | ↓ | ↓ |
| Normal values pHα kidney lung | 7.35–7.45 | 35–45 | 24–26 | 25–28 |

Metabolic acidosis occurs in such conditions as diabetes (in which there is an accumulation of keto acids); renal failure, when the kidney is unable to excrete hydrogen ion; diarrhea from loss of base; and tissue hypoxia associated with lactic acid accumulation. When pH falls, respiration is stimulated so that $PCO_2$ will decrease and tend to compensate for the reduction in pH. This compensation is usually incomplete, and pH remains below 7.35. The pH, carbon dioxide content ($HCO_3^-$ $PCO_2$), $HCO_3^-$, and $PCO_2$ are all reduced.

Metabolic alkalosis occurs most commonly after excessive loss of HCl due to vomiting (as in pyloric stenosis) or after an excessive citrate or bicarbonate load. The carbon dioxide content is elevated, and the $PCO_2$ will be normal or elevated depending on the chronicity of the alkalosis.

Acute respiratory acidosis is secondary to respiratory insufficiency and accumulation of carbon dioxide within the body. The associated acidosis may be compensated for by renal adjustments that promote retention of $HCO_3^-$. Compensation may require several days. Patients in chronic respiratory acidosis who receive therapy that improves alveolar ventilation will have a decrease in their $PaCO_2$, but their adjustment in bicarbonate will be much slower, resulting in a metabolic alkalosis of several days' duration. A simple rule is that if hypercarbic respiratory failure has occurred over many days, such that compensation has occurred, the clinician should slowly normalize the $PaCO_2$ to avoid excessive metabolic alkalosis.

Acute respiratory alkalosis (e.g., secondary to fever, psychogenic hyperventilation, or a pontine lesion with meningoencephalitis) is associated with high pH, low $PCO_2$, and normal bicarbonate level. Renal compensation in time leads to excretion of bicarbonate and return of pH toward normal.

It is important to point out that the lung excretes some 300 mEq/kg of acid per day in the form of carbon dioxide, and the kidney excretes 1 to 2 mEq/kg/day. Thus, the lung plays a large role in the acid-base balance of the body, in fact providing rapid adjustment when necessary. The Henderson-Hasselbalch equation may be thought of as

$$pH \alpha \frac{kidney}{lung}$$

## Difference Between Additions of $CO_2$ to Blood *in vitro* and *in vivo*

An appreciation of the difference between the so-called *in vitro* and *in vivo* $CO_2$ dissociation curves is necessary to clarify the confusion that has arisen regarding the interpretation of measurements of acid-base balance, particularly during acute respiratory acidosis (acute hypoventilation). When blood *in vitro* is equilibrated with increasing concentrations of $CO_2$, bicarbonate concentration also increases because of the hydration of carbon dioxide. If, for example, blood with a $PCO_2$ of 40 mm Hg and a bicarbonate concentration of 24 mEq/L was equilibrated with a $P_{CO_2}$ of 100 mm Hg, the actual bicarbonate concentration would be measured as 34 mEq/L. In the Astrup nomogram, a correction for this increased bicarbonate due to $CO_2$ alone is made, and the standard bicarbonate (bicarbonate concentration at $P_{CO_2}$ of 40 mm Hg) is considered to be 24 mEq/L or a base excess of zero. With this correction, one can readily see that the metabolic (renal) component of acid-base balance is normal. However, confusion has arisen because the *in vitro* correction figures have been incorrectly applied to the situation *in vivo.* Unlike equilibration in the test tube, the additional bicarbonate generated during *in vivo* acute hypercapnia not only is distributed to water in red blood cells and plasma but also equilibrates with the interstitial fluid space; that is, bicarbonate ion equilibrates with extracellular water. If the interstitial fluid represents 70% of extracellular water, then 70% of the additional bicarbonate generated will be distributed to the interstitial fluid. Thus, an arterial sample taken from a patient with an acute elevation of $P_{CO_2}$ to 100 mm Hg would have an actual bicarbonate concentration of 27 mEq/L. If 10 mEq/L were subtracted according to the *in vitro* correction, the standard bicarbonate would be reported as 17 mEq/L or a base excess of −7, which would indicate the presence of metabolic as well as respiratory acidosis. This conclusion would be incorrect; actually, the bicarbonate concentration *in vivo* is appropriate for the $P_{CO_2}$. The situation is worse in the newborn infant because of the high hematocrit and large interstitial fluid space. Base excess values of as much as −10 mEq/L (standard bicarbonate 14 mEq/L) may be calculated despite the fact that the *in vivo* bicarbonate concentration is appropriate for the particular $P_{CO_2}$ and there is no metabolic component to the acidosis. Thus, the appropriate therapy is to increase alveolar ventilation and not to administer bicarbonate.

# Tissue Respiration

## Aerobic Metabolism

The ultimate function of the lung is to provide oxygen to meet the demands of the tissues and to excrete carbon dioxide, a by-product of metabolic activity. Thus, respiratory physiologists have been concerned with the assessment of respiration at the tissue level and the ability of the cardiopulmonary system to meet the metabolic demands of the body.

One method is to measure the amount of oxygen consumed by the body per minute ($\dot{V}O_2$). This is equal to the amount necessary to maintain the life of the cells at rest, plus the amount necessary for oxidative combustion required to maintain a normal body temperature, as well as the amount used for the metabolic demands of work above the resting level. The basal metabolic rate is a summation of many component energy rates of individual organs and tissues and is defined as the amount of energy necessary to maintain the life of the cells at rest under conditions in which there is no additional energy expenditure for temperature regulation or additional work.

In practice, $\dot{V}O_2$ is measured after an overnight fast, the subject lying supine in a room at a comfortable temperature. This “basal” metabolic rate has a wide variability (± 15% of predicted $\dot{V}O_2$). Since absolutely basal conditions are difficult to ensure, the measurement of basal metabolic rate is not widely used at present.

The performance of the cardiopulmonary system can be more adequately assessed and compared with normal measurements under conditions of added work, such as exercise. During exercise, healthy subjects demonstrate an improvement in pulmonary gas exchange, cardiac output, and tissue oxygen extraction. Performance can be increased by physical fitness, and athletes are able to increase their cardiac output by sixfold or sevenfold. In children, the relationship between work capacity, ventilation, and oxygen consumption is the same as that in the adult. The maximal $\dot{V}O_2$ that can be achieved increases throughout childhood, reaches its peak of 50 to 60 mL/min/kg between 10 and 15 years of age, and thereafter declines slowly with age. Different individuals are endowed with different maximal $\dot{V}O_2$ and, although bed rest will significantly decrease $\dot{V}O_2$, even vigorous training only minimally increases an individual's inherent $\dot{V}O_2$.[67]

At the tissue level, the ability of a given cell to receive an adequate oxygen supply depends on the amount of local blood flow, the distance of the cell from the perfusing capillary, and the difference between the partial pressures of oxygen in the capillary and in the cell. The critical mean capillary $PO_2$ appears to be in the region of 30 mm Hg for children and adults. Exercising muscle has 10–20 times the number of open capillaries as resting muscle does.

The body's response to exercise therefore is complex and depends on the amount of work, the rate at which the workload is increased, and the subject's state of health and degree of physical fitness. A detailed description of the physiologic response to exercise and its use in diagnosing cardiorespiratory disease is beyond the scope of this chapter, but exercise testing is now an important tool in clinical medicine (see Chapter 12).

## Anaerobic Metabolism

The adequacy of oxygen supply to the tissues has been assessed by measuring blood lactate, a product of anaerobic metabolism (Embden-Meyerhof pathway). When there is an insufficient oxygen supply to the tissues due to either insufficient blood flow or a decrease in blood oxygen content, lactic acid concentration within the tissues and blood increases. In the blood, this accumulation leads to metabolic acidosis.

During moderate to heavy muscular exercise, cardiac output cannot meet the demands of the muscles, and an oxygen debt is incurred, which is repaid on cessation of exercise. During this period, lactic acid accumulates, and therefore rigorous exercise is often associated with metabolic acidosis. There is an excellent correlation between the serum lactate level and the oxygen debt. Oxygen debt is not measurable at rest and is difficult to measure during exercise, but the adequacy of tissue oxygenation appears to be accurately reflected in the serum lactate level. In adult humans, blood lactate is less than 1 mEq/L but may increase to 10 to 12 mEq/L during very heavy exercise.

## Relationship between $\dot{V}o_2$ and $\dot{V}co_2$

In the normal subject in a steady state, the amount of carbon dioxide excreted by the lung per minute depends on the basal metabolic activity of the cells and the type of substrate being oxidized. The volume of carbon dioxide exhaled divided by the amount of oxygen consumed is known as the respiratory exchange ratio (R). For the body as a whole, the ratio is 1 if primarily carbohydrate is being metabolized, 0.7 if fat, and 0.8 if protein. Normally, the ratio is 0.8 at rest, approximately 1.0 during exercise, and greater than 1 at exhaustion when there is anaerobic metabolism. The respiratory exchange ratio may vary considerably with changes in alveolar ventilation and metabolism and therefore must be measured in the steady state (i.e., with a steady alveolar ventilation and a steady metabolic rate). For an individual organ, the metabolic respiratory quotient ($\dot{R}\dot{Q}$) is nearly constant but may vary from 0.4 to 1.5, depending on the balance of anabolism and catabolism in that organ. Thus, the measurement of R represents the result of many component-metabolizing organs and tissues. After birth, R decreases from nearly 1 to 0.7, indicating a loss of carbohydrate stores; when feeding has started, R approaches 0.8.

With breath-by-breath $CO_2$ and $O_2$ concentrations, R can be calculated on a breath-by-breath basis. Using this technique, it is possible to define more precisely the workload at which anaerobic metabolism begins (threshold for anaerobic metabolism). As lactic acid begins to accumulate in the blood, the carbon dioxide dissociation curve shifts to the right, and there is a sudden increase in expired $CO_2$. R therefore suddenly increases from about 1.0 to above 1.0. It has been shown that the threshold for anaerobic metabolism in both adults and children can be increased by training. This technique is particularly useful in children, because it does not require blood sampling and can be readily applied to cooperative subjects with a variety of pulmonary and cardiac problems.

## Regulation of Respiration

The regulation of respiratory rhythm[68] and its control have been extensively studied over the past decades including its abnormalities in diseases such as congenital hypoventilation syndrome[69] caused by Phox2b mutations, sudden infant death syndrome,[70] and sleep disorders.[71,72] A brief discussion is provided later in the chapter, but further details are available in the references cited[70–72] and in Chapters 80 and 81.

The study of the regulation of respiration centers around three main ideas: (1) the generation and maintenance of a respiratory rhythm, (2) the modulation of this rhythm by a number of sensory feedback loops and reflexes, and (3) the recruitment of respiratory muscles that can contract appropriately for gas exchange (Fig. 6.29).

**FIG. 6.29** Schematic diagram of the respiratory control system. (From Fishman AP. *Pulmonary Diseases and Disorders*. New York: McGraw-Hill; 1980.)

The central nervous system, particularly the brainstem, has the inherent ability to function as the respiratory "sinus node," or the source of central pattern generation. The pacemaker neurons are located within the brainstem's preBötzinger Complex (preBötC) and are the main source of inspiratory rhythm. Each part of the respiratory cycle is controlled by distinct groups of neurons that interact dynamically with some stimulating, some inhibiting, and others having their effect dependent upon the phase of the respiratory cycle. The overall control of respiratory rhythm is influenced by many factors, including cortical behavioral influences; sleep state; peripheral and central chemoreceptors; and receptors within the lungs, joints, and muscles.

## Sensory Feedback System

The respiratory system is endowed with a wealth of afferent pathways to maintain control over several functional variables and adjust them at appropriate times. These pathways inform the central pattern generator about instantaneous changes that take place in, for example, the lungs, the respiratory musculature, the blood (acid-base), and the environment. The terms *sensory* and *afferent* refer not only to peripheral but also to central systems converging on the brainstem respiratory neurons.

Cutaneous or mucocutaneous stimulation of the area innervated by the trigeminal nerve (e.g., the face, nasal mucosa) decreases respiratory frequency and may lead to the generation of respiratory pauses. These respiratory effects become less important with age, their strengths are species-specific, and they depend on the state of consciousness. Because cortical inhibition of the trigeminal afferent impulses is more pronounced during REM sleep, trigeminal stimulation has a greater effect on respiration during quiet (non-REM) sleep.

The laryngeal receptor reflex is probably the most inhibitory reflex on respiration known. Sensory receptors are present in the epithelium of the epiglottis and upper larynx. Introduction into the larynx of small amounts of water or solutions with low concentrations of chloride will result in apnea. The duration and severity of the respiratory changes depend on the behavioral state and are exacerbated by the presence of anesthesia. They are also worse if the subject is anemic, hypoglycemic, or a premature infant. In the unanesthetized subject, the reflex effects are almost purely respiratory and are mediated by the superior laryngeal nerve, which joins the vagal trunk after the nodose ganglion.

Rapidly adapting, slowly adapting, and J receptors (vagal) are present in the tracheobronchial tree and lung interstitial space and were described earlier in this chapter. These play an important role in informing the central nervous system about the status of lung volume, tension across airways, and lung interstitial pressure. Stretch receptors, when stimulated by lung inflation, prolong expiratory duration and delay the start of the next inspiration. J receptors are stimulated by lung edema, and they produce tachypnea with interspersed short periods of respiratory pauses.

## $O_2$ and $CO_2$

The respiratory control system also receives information about $O_2$ and $CO_2$ tensions from sensory receptors located in specialized neural structures in blood vessels, airways, and the central nervous system.

Central chemoreceptors are located in the ventral lateral medulla, and increases in $P_{CO_2}$ or $H^+$ concentration produce an increase in ventilation; conversely, a decrease in $P_{CO_2}$ or $H^+$ concentration causes a depression of ventilation. This area is influenced primarily by the acid-base composition of cerebral spinal fluid (CSF), and the delay in ventilatory response to changes in arterial $P_{CO_2}$ and bicarbonate is due to the time required to change the CSF $H^+$ concentration. Carbon dioxide, which diffuses into the CSF in a few minutes, has a rapid effect on the central chemoreceptors. Changes in blood bicarbonate are much less rapidly reflected in the CSF (24 to 48 hours). Thus, with acute metabolic acidosis, arterial $P_{CO_2}$ decreases along with CSF $P_{CO_2}$. Hyperventilation is produced by the $H^+$ stimulation of peripheral chemoreceptors, but this stimulus is inadequate to compensate fully for the metabolic acidosis because of inhibition from the decreased $H^+$ concentration in the CSF. After 24 hours, CSF bicarbonate decreases and restores CSF pH to normal. There is a further decrease in arterial $P_{CO_2}$, and arterial pH returns toward normal. From these observations, it has been suggested that the control of alveolar ventilation is a function of the central chemoreceptors, which are under the influence of CSF or brain interstitial fluid $H^+$, acting in association with the peripheral chemoreceptors, which are directly under the influence of the arterial blood.

The peripheral chemoreceptors are found in the human along the structures associated with the branchial arches. Two sets of chemoreceptors appear to be of greatest physiologic importance: (1) the carotid bodies, which are located at the division of the common carotid artery into its internal and external branches, and (2) the aortic bodies, which lie between the ascending aorta and the pulmonary artery. Afferent nerves from the carotid body join the glossopharyngeal (IX) nerve; those from the aortic bodies join the vagosympathetic trunk along with the recurrent laryngeal nerves.

The carotid and aortic bodies are responsive primarily to changes in the $PO_2$. At rest, they are tonically active, signifying that some ventilatory drive exists even at a $PaO_2$ of 100 mm Hg. Inhalation of low oxygen mixtures is associated with a significant increase in ventilation when the $PaO_2$ is less than 60 mm Hg. Potentiation of the hypoxic stimulus is achieved by an increase in $PaCO_2$. The response of the peripheral chemoreceptors to $PCO_2$ is rapid (within seconds), and ventilation increases monotonically with $PaCO_2$. The rate of the change in $PaCO_2$ may be as important as the change. The peripheral chemoreceptors, also responsive to changes in arterial pH, increase ventilation in association with a decrease of 0.1 pH unit and produce a twofold to threefold increase with a decrease of 0.4 pH unit. A variety of peripheral reflexes are known to influence respiration. Hyperpnea may be produced by stimulation of pain and temperature receptors or mechanoreceptors in limbs. Visceral reflexes (e.g., those that result from distention of gallbladder or traction on the gut) are usually associated with apnea. Afferent impulses from respiratory muscles (e.g., intercostals) may play a role in determining the optimum response of the muscles of ventilation to various respiratory stimuli. In newborn infants, an inspiratory gasp may be elicited by distention of the upper airways. This reflex is mediated by the vagus nerve and is known as the *Head reflex.* It has been suggested that this inspiratory gasp reflex is important in the initial inflation of the lungs at birth.

## The Newborn Infant

A number of studies have demonstrated that the responsiveness to stimuli in newborn infants is different from that of older or mature adult subjects. Although the exact mechanisms for these differences have generally been elusive, the rapid maturational changes that occur in key control systems could serve as the bases for the different responses seen in early life. Similar to adults, infants increase ventilation in response to inspired carbon dioxide, and peripheral chemoreceptors are functional in newborn infants, as demonstrated by a slight decrease in VE with 100% oxygen breathing. The effect of hypoxia as a stimulant may differ in the first 12 hours of life; 12% oxygen in the first 12 hours of life fails to stimulate ventilation. In addition, it has been found that the newborn infant will increase ventilation only transiently in response to a hypoxic stimulus; ventilation rapidly falls below baseline. In adults, the increase in ventilation is maintained above basal levels, although it lessens with time.

The mechanisms responsible for this different response to hypoxia in the newborn are not well understood. The biphasic hypoxic response is likely multifactorial and may be due to one or more of the following: (1) reduction in dynamic lung compliance, (2) reduction in chemoreceptor activity during sustained (>1 to 2 min) hypoxia, (3) central neuronal depression due to either an actual drop in excitatory synaptic drive other than carotid input or changes in neuronal membrane properties reducing excitability, and (4) decrease in metabolic rate.

## Metabolic Functions of the Lung

The lungs have important nonrespiratory functions, including phagocytosis by alveolar macrophages, filtering of microemboli from blood, biosynthesis of surfactant components, and excretion of volatile substances. An equally important nonrespiratory function is the pharmacokinetic function of the pulmonary vascular bed: the release, degradation, and activation of vasoactive substances. The lung is ideally situated for regulating the circulating concentrations of vasoactive substances, because it receives the entire cardiac output and possesses an enormous vascular surface area. As Table 6.6 illustrates, the pulmonary vascular bed not only handles a wide variety of compounds (amines, peptides, lipids), but it also is highly selective in its metabolic activity. For example, norepinephrine is metabolized by the lung, whereas epinephrine, which differs from it only by a methyl group, is unaffected by passage through the pulmonary circulation.

**Table 6.6**

**Handling of Biologically Active Compounds by the Lung**

| | |
|---|---|
| Metabolized at the endothelial surface without uptake | Bradykinin<br>Angiotensin I<br>Adenine nucleotides |
| Metabolized by the endothelial cell after uptake | Serotonin<br>Norepinephrine<br>Prostaglandins E and F |
| Unaffected by passage through the lung | Epinephrine<br>Dopamine<br>Angiotensin II<br>Vasopressin |
| Released by the lung | Prostaglandins (e.g., prostacyclin)<br>Histamine<br>Kallikrein |

The physiologic consequences of the metabolic functions of the lung can be illustrated by angiotensin-converting enzyme (ACE). A peptidase located on the surface of the endothelial cell, ACE is responsible for the degradation of bradykinin, a potent vasodilator and edematogenic peptide, and for the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. Angiotensin II production influences systemic blood pressure at all ages but is especially important during the neonatal period, because sympathetic innervation is incompletely developed.

## Acknowledgments

In the previous seven editions of this chapter, the authors have included Mary Ellen Avery, Victor Chernick, Hugh O'Brodovich, Gabriel Haddad, and John West. This chapter has incorporated some information from the late Dr. Mary Ellen Wohl's chapter on Developmental Physiology of the Lung, which appeared in previous editions.

## 7

# Biology and Assessment of Airway Inflammation

*Sejal Saglani BSc, MBChB, MD, Clare M. Lloyd PhD, Andrew Bush MB BS(Hons), MA, MD, FRCP, FRCPCH, FERS*

## Introduction

Inflammation is classically characterized by four cardinal signs: *calor*, *rubor* (due to vasodilatation), *tumor* (due to plasma exudation and edema), and *dolor* (due to sensitization and activation of sensory nerves. Inflammation is also characterized by infiltration with several types of effector cells, which differ depending on the type of inflammatory process. A normal inflammatory response is essential to allow protection of the body against invasion from external environmental insults such as microorganisms, toxins, and pathogens. Failure of any of the components of the inflammatory response (e.g., neutrophil dysfunction, also known as Job's syndrome) has catastrophic consequences. The inflammatory response not only provides an acute defense against injury (proinflammatory) but is also involved in the healing and restoration of normal function after tissue damage from infection and toxins (regulatory).

Cystic fibrosis (CF) bronchiectasis and persistent bacterial bronchitis are characterized by a neutrophilic pattern of inflammation, driven in part by chronic bacterial infection; and the pathophysiology is covered in more detail in Chapters 49 and 51.

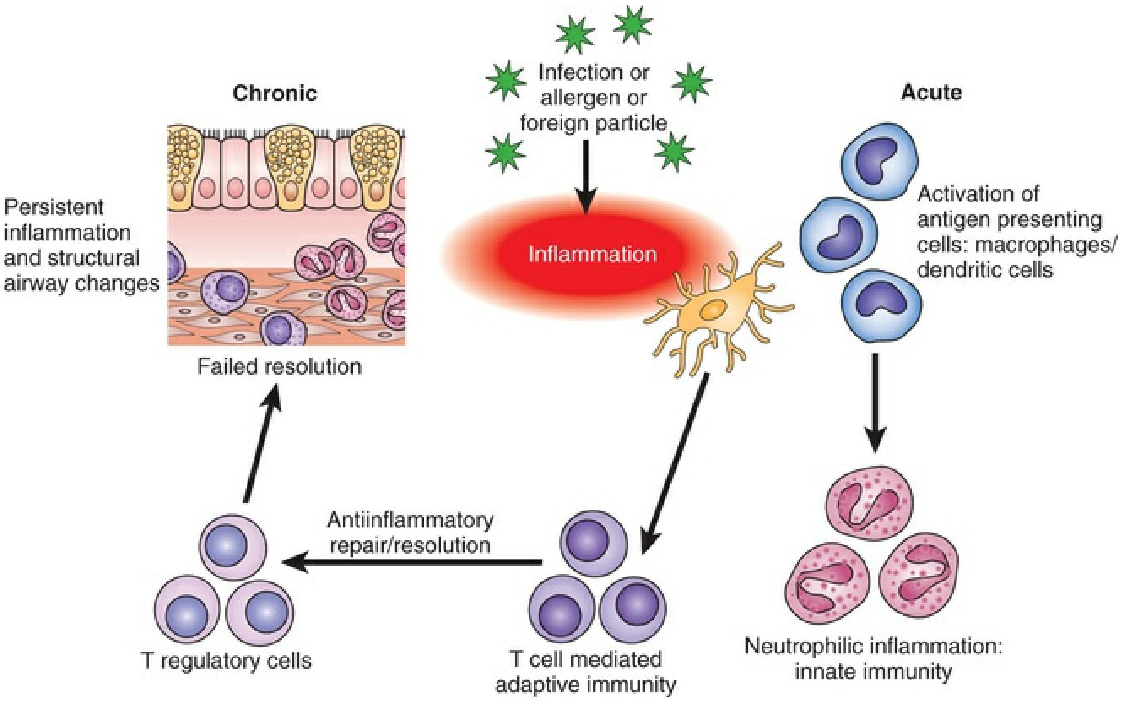
## Allergic Inflammation

Allergic inflammation develops following exposure to allergens and is mediated mainly by IgE-dependent mechanisms, resulting in a characteristic pattern of inflammation characterized by eosinophils and mast cells. Details of the development of the allergic inflammatory response, specifically in the context of asthma, are described in Chapter 43. The allergic inflammatory response is unusual, as it develops to innocuous environmental agents such as house dust mite, pollen, and peanut. The development of an allergic inflammatory response is therefore inappropriate and is harmful rather than beneficial, and it results in allergic diseases such as asthma or atopic dermatitis. The inflammatory response seen in allergic diseases is characterized by an infiltration with eosinophils[1] and resembles the inflammatory process in parasitic infections. For some reason, allergens such as house dust mite and pollen proteins activate eosinophilic inflammation, possibly because of their protease activity. Normally, such an inflammatory response would kill the invading parasite (thus preventing the parasite from overwhelming the host) and the process would be self-limiting, but in allergic diseases, the inciting stimulus persists and the acute inflammatory response turns into chronic inflammation, with structural consequences in the airways and skin.[2,3]

## Acute Inflammation

Acute inflammation in the respiratory tract is an immediate defense reaction to inhaled allergens, pathogens, or noxious agents. The structural integrity of the respiratory tract is vital to preventing infection with inhaled microorganisms. Important mechanisms including an intact respiratory epithelium, mucus production, and mucociliary clearance via the action of cilia and cough act to prevent infection with respiratory pathogens. The importance of these mechanisms in host defense is highlighted by high rates of bacterial infection in conditions such as cystic fibrosis and primary ciliary dyskinesia (PCD), which are characterized by abnormal mucociliary function, either as primary or secondary phenomena.

Immune cells such as neutrophils and alveolar macrophages are present in large numbers in the airways and constitute a first line of defense against respiratory pathogens. Macrophages recognize microorganisms via the presence of surface receptors such as toll-like receptors (TLRs) leading to phagocytosis, microbicidal killing, and initiation of immune responses.[4] Components of the bacterial cell wall are recognized by toll-like receptor 4, which is present on macrophages and leads to macrophage activation and phagocytosis. In addition, the membrane protein P2, recognized by toll-like receptor 2 is a specific trigger of macrophage activation, and results in secretion of interleukin 8 (IL-8) and tumor necrosis factor-$\alpha$ (TNF-$\alpha$) with subsequent recruitment of neutrophils to the site of infection (Fig. 7.1).



Infection or allergen or foreign particle
Chronic
Acute
Persistent inflammation and structural airway changes
Inflammation
Activation of antigen presenting cells: macrophages/ dendritic cells
Failed resolution
Antiinflammatory repair/resolution
T regulatory cells
T cell mediated adaptive immunity
Neutrophilic inflammation: innate immunity

**FIG. 7.1** Development of acute and chronic inflammation. Inhaled foreign environmental particles result in the development of an acute inflammatory response by antigen presenting cells (dendritic cells) and innate immune cells such as macrophages. This

leads to the induction of an adaptive immune response by conversion of naïve T cells to T helper cells in the lymph nodes. The acute inflammatory response is followed by a process of active repair and resolution; however, if this fails, as is the case in inflammatory diseases, a cycle of sustained chronic inflammation develops resulting in disease pathology.

Inhalation of an allergen (e.g., house dust mites) activates surface mast cells by an IgE-dependent mechanism. This releases multiple bronchoconstrictor mediators, resulting in rapid contraction of airway smooth muscle and wheezing.[5] These mediators also result in plasma exudation, edema of the airways and recruitment of inflammatory cells from the circulation—particularly eosinophils, neutrophils (transiently), and T-lymphocytes, mainly of the T helper 2 (Th2) type. This accounts for the late response that occurs 4–6 hours after allergen exposure and resolves within 24 hours, which should be regarded as an acute inflammatory reaction. The acute inflammatory response in the respiratory tract is usually accompanied by increased mucus secretion, which is a part of the defense system that protects the delicate mucosal surface of the airways.

## Chronic Inflammation

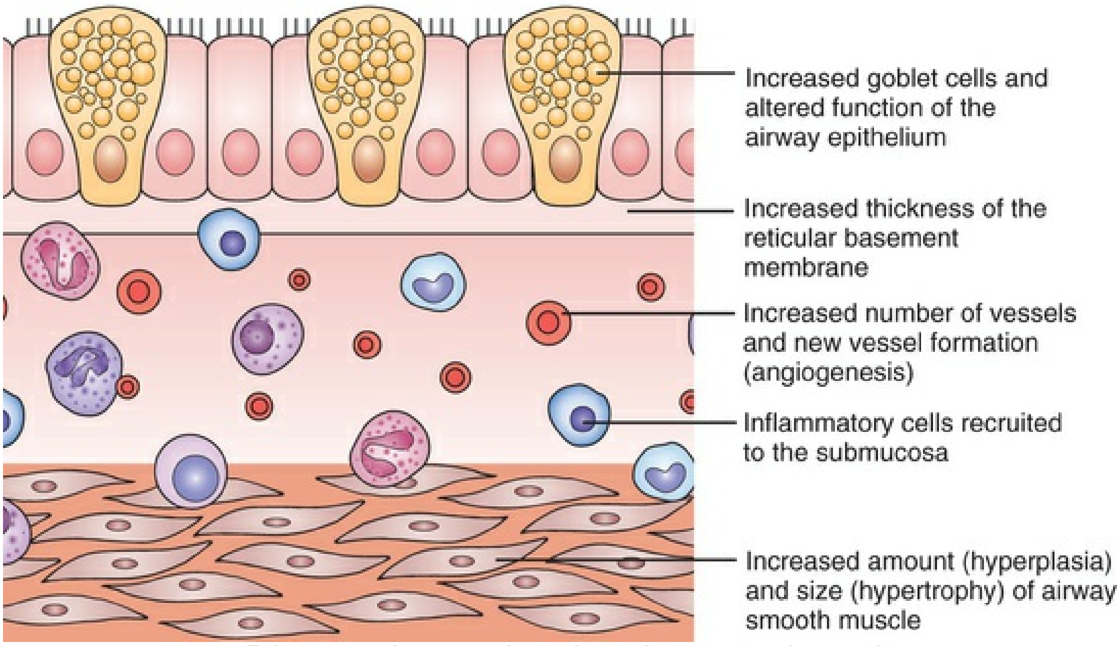
The normal consequence of an acute inflammatory process is complete resolution; for example, acute lobar pneumonia due to pneumococcal infection is characterized by a massive influx of neutrophils, with complete resolution and restoration of normal lung structure. However, many airway inflammatory conditions are chronic and result from an exaggerated inflammatory response with failed or inadequate resolution. In certain airway infections such as pulmonary tuberculosis, there may be a prolonged and inappropriate period of acute neutrophilic inflammation, with a failure of development of chronic inflammation that results in pathology.[6] An imbalance between proinflammatory responses and regulatory responses results in pathologic chronic inflammatory airways diseases, and this chronic inflammatory process may persist even in the absence of causal mechanisms (see Fig. 7.1).

Examples include occupational asthma in which the pathological process and symptoms continue despite complete avoidance of sensitizing agents and in adult patients with chronic obstructive pulmonary disease who have persistent airway inflammation, even after stopping smoking for many years.

The resolution of inflammation was previously thought to be a passive process, but it is now realized that there are important active control mechanisms. Several potential mechanisms are important in the normal resolution of inflammation. These include IL-10,[7,8] CD200,[9,10] Annexin,[11] lung Kruppel-like factor (LKLF),[12] lipid mediators such as Resolvin E1 (RvE1), Protectin D1 (PD1), and Lipoxin $A_4$ ($LXA_4$), interferon (IFN)-$\gamma$, and the IL-23 axis,[13,14] These mediators and regulators will be discussed in more detail in the following paragraphs. The molecular and cellular mechanisms for the persistence of inflammation in the absence of its original causal mechanisms are not fully understood, but they presumably involve some type of long-lived immunologic memory that drives the inflammatory process. Structural cells, such as airway epithelial and airway smooth muscle cells, are also immunologically active and can drive the chronic inflammatory process (see Fig. 7.1). This is a key area of research, as understanding these mechanisms might lead to potentially curative therapies.

## Structural Changes and Repair

A repair process that restores the tissue to normal usually follows the acute inflammatory response. This may involve proliferation of damaged cells (e.g., airway epithelial cells) and fibrosis to heal any breach in the mucosal surface.[15] These repair processes may also become chronic in response to continued inflammation, resulting in “exaggerated” structural changes in the airways that are referred to as *remodeling.*[16] However, the relationship between airway inflammation and remodeling is controversial; the conventional view—that inflammation leads to remodeling—has been challenged by human and animal work, which suggests that they may be parallel processes.[17–19] These structural changes in asthma and CF may result in irreversible narrowing of the airways, with fixed obstruction to air flow. In asthma, several structural changes are found in the airway wall, including increased thickness of the subepithelial basement membrane, an increased amount of airway smooth muscle, and an increased number of blood vessels (angiogenesis) (Fig. 7.2). There is much debate about the importance of airway remodeling in asthma, as it is not seen in all patients. It may contribute to airway hyperresponsiveness (AHR) in asthma, but it may also have some beneficial effects in limiting airway closure.[20] Details of each of the structural changes seen in children with asthma and their functional relevance, particularly the role of structural airway cells in mediating inflammation, are provided in Chapter 43.

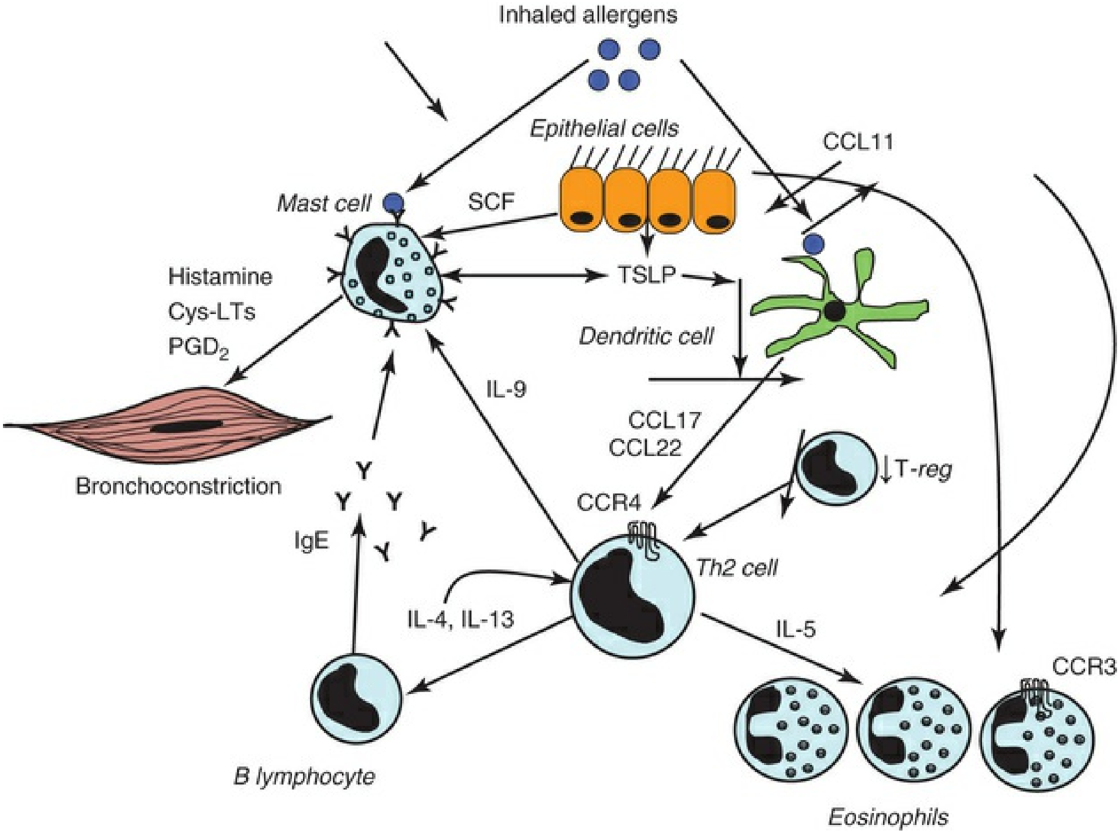


Increased goblet cells and altered function of the airway epithelium
Increased thickness of the reticular basement membrane
Increased number of vessels and new vessel formation (angiogenesis)
Inflammatory cells recruited to the submucosa
Increased amount (hyperplasia) and size (hypertrophy) of airway smooth muscle

**FIG. 7.2** Diagram illustrating the airway pathological changes in asthma.

## Inflammatory Cells

Many types of inflammatory cells are involved in airway inflammation, and the functional roles of each cell type and the interrelationship among cells are complex and not completely understood (Fig. 7.3). Chronic inflammatory airways diseases can be divided into those that are predominantly neutrophilic or eosinophilic. Chronic suppurative lung diseases such as CF and PCD demonstrate predominantly neutrophilic inflammation, which may be present even in the absence of detectable infection (at least by conventional culture). This “sterile” inflammation is associated with structural airway damage and is thought to lead to bronchiectasis.[21] Interestingly, in CF, while the predominant inflammatory cell in the airway lumen is the neutrophil (as shown by sputum and bronchoalveolar lavage cytology), T-lymphocytes predominate in the proximal airway wall.[22]



Inhaled allergens
Epithelial cells
CCL11
Mast cell

Th2 cell
IL-4, IL-13
IL-5
CCR3
B lymphocyte
Eosinophils

**FIG. 7.3** Inflammation in asthma. Inhaled allergens activate sensitized mast cells by cross-linking surface-bound IgE molecules to release several bronchoconstrictor mediators, including cysteinyl-leukotrienes *(cys-LT)* and prostaglandin D$_2$ *(PGD$_2$).* Epithelial cells release stem-cell factor *(SCF),* which is important for maintaining mucosal mast cells at the airway surface. Allergens are processed by myeloid dendritic cells, which are conditioned by thymic stromal lymphopoietin *(TSLP)* secreted by epithelial cells and mast cells to release the chemokines CC-chemokine

ligand 17 *(CCL17)* and *CCL22*, which act on CC-chemokine receptor 4 *(CCR4)* to attract T helper 2 *(Th2)* cells. Th2 cells have a leading role in orchestrating the inflammatory response in allergy through the release of interleukin-4 *(IL-4)* and *IL-13* (which stimulate B cells to synthesize IgE), *IL-5* (which is necessary for eosinophilic inflammation), and *IL-9* (which stimulates mast-cell proliferation). Epithelial cells release *CCL11*, which recruits eosinophils via *CCR3.* Patients with asthma may have a defect in regulatory T cells *(T-reg)*, which may favor further Th2-cell proliferation.

The predominant inflammatory cell pattern seen in children with asthma is eosinophilic since the majority of children have allergic asthma. The same kind of inflammation is seen in bronchial biopsies in children as in adults, which indicates that similar inflammatory mechanisms are likely.[18,23–27] However, inflammatory phenotypes are heterogeneous and may vary between children and over time in the same children.[28] Adults with severe asthma appear to have a predominantly neutrophilic inflammatory profile. In contrast, as a group, children with severe asthma have eosinophilic airway inflammation during stable disease. However, little is known about changes in the airway inflammatory profile in children with asthma during exacerbations, but since most exacerbations are precipitated by infection, it is likely that the patterns of inflammation change, and this may explain the relative inefficacy of steroids during exacerbations, particularly in children with severe disease. A specific phenotype in which efficacy of steroids can be very variable is preschool wheeze. The inflammatory mechanisms in early wheeze, especially episodic (viral) wheeze, are little studied or understood. It is known that preschool children with severe recurrent wheezing, which is present both during and in between respiratory infections (multiple trigger wheeze), have an airway eosinophilia during stable disease.[18] The pattern of inflammation during acute episodes remains unclear. In addition, the inflammatory pattern seen at bronchoscopy is the same in children with multiple trigger (asthmatic) wheeze, independent of their atopic status.[29] The evidence in episodic (viral) wheeze suggests that the pattern is neutrophilic.[30–33] No single inflammatory cell accounts for the complex pathophysiology of asthma, although some cells predominate in allergic inflammation; and inflammation might vary in different compartments of the lung. In adults with asthma, transbronchial biopsy has shown evidence of very distal inflammation in the absence of proximal airway inflammation; there are no equivalent pediatric studies.[34–36] There is also a dissociation between airway mucosal (wall) and airway luminal inflammatory patterns in asthma.[37]

## Mast Cells

Mast cells are important in initiating the acute bronchoconstrictor responses to allergens[38] and probably to other indirect stimuli such as exercise and hyperventilation (via osmolality or thermal changes). Treatment of asthmatic patients with prednisolone results in a decrease in the number of tryptase-positive mast cells. Furthermore, mast cell tryptase appears to play a role in airway remodeling, as this mast cell product stimulates human lung fibroblast proliferation. Mast cells also secrete cytokines, including IL-4 and eotaxin, which may be involved in maintaining the allergic inflammatory response and the TNF-$\alpha$.[39] Mast cells are found in increased numbers in airway smooth muscle of asthmatic patients, and this appears to correlate with AHR, suggesting that mast cell mediators may mediate AHR.[40]

However, mast cells may play less of a role in chronic allergic inflammatory events, and it seems more probable that other cells, such as macrophages, eosinophils, and T-lymphocytes, are important in the chronic inflammatory process and in AHR. Classically, allergens activate mast cells through an IgE-dependent mechanism. The importance of IgE in the pathophysiology of asthma has been underscored by recent clinical studies with humanized anti-IgE antibodies, which inhibit IgE-mediated effects. Anti-IgE therapy is effective in patients, including children, with severe asthma who are not well controlled by high doses of corticosteroids; and it is particularly effective in reducing exacerbations.[41] The relationship between IgE and mast cell degranulation in causing acute allergic responses is discussed in

Chapter 43, and the role of omalizumab (anti-IgE monoclonal antibody) in the treatment of severe asthma is discussed in Chapter 48.

## Macrophages

The alveolar macrophage (AM) is the most numerous immune cell present within the respiratory tract. Originally thought to be derived from peripheral monocytes, current knowledge of their function is largely based upon studies of macrophages derived from peripheral precursors. Recent evidence, however, suggests that AMs enter the lungs prenatally and proliferate *in situ*,[42–44] suggesting highly specialized functions. It is now apparent that local tissue milieu and regulatory influences result in macrophages that have very specific phenotypes and functions.[45,46] Bone-marrow derived macrophages have been shown to differentiate to an AM phenotype following pulmonary transplantation, confirming the importance of the local environment in phenotypic development[47]; however, the mechanisms by which this occurs are poorly understood. Airway macrophages are ideally positioned to dictate the innate defense of the airways (Fig. 7.4). Pulmonary macrophage populations are heterogeneous and demonstrate plasticity, owing to variations in origin, tissue residency, and environmental influences. The diversity of pulmonary macrophages facilitates efficient responses to environmental signals and allows rapid alterations in phenotype and in response to a plethora of cytokines and microbial signals.[48] They express a wide range of receptors, which enable them to regulate their local environment by responding to changes within it. These receptors can be activating, such as TLRs to sense pathogens and cytokine receptors for TNF, IL-1, and IFNγ. Alternatively, the receptors may be suppressive, such as CD200, Triggering Receptor Expressed on Myeloid Cells (TREM), and transforming growth factor-β (TGF-β). The receptors enable high level of engagement and interaction with pulmonary epithelial cells. Indeed, this interaction is crucial for maintenance of immune homeostasis within the respiratory tract. Cooperation between the cells facilitates clearance of cellular debris and particulate matter, as well as directing specific immune responses to pathogens.

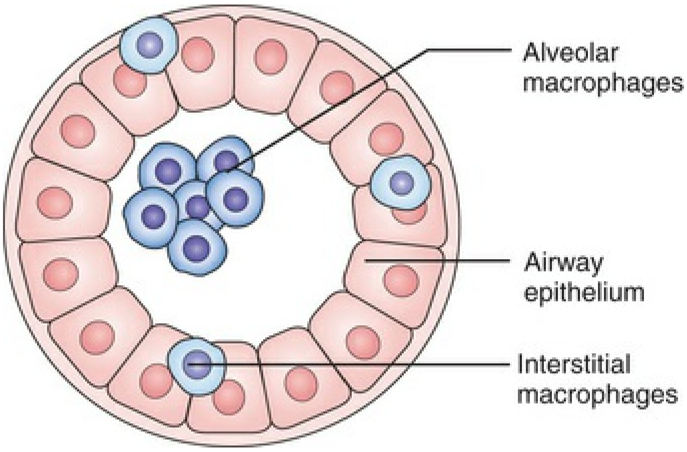

**FIG. 7.4** Interstitial and alveolar macrophages in airway to maintain immune homeostasis. Immune cells are present in the airways and constantly undertaking immune surveillance to ensure homeostasis and on standby to initiate an inflammatory response to foreign particles when needed. Both interstitial *(red)* and alveolar *(blue)* macrophages perform continued immune surveillance in the lungs to maintain immune homeostasis.

Macrophages have the capacity to secrete a large variety of different agents with either proinflammatory or antiinflammatory effects, including cytokines and growth factors, chemotactic factors, lipid mediators, and proteinases. In asthma, macrophages may be activated by allergens via low-affinity IgE receptors (Fcε;RII [Receptor II]). The vast immunologic repertoire of macrophages allows them to produce more than 100 different products, including a large variety of cytokines that may orchestrate the inflammatory response. Macrophages have the capacity to initiate a particular type of inflammatory response via the repertoire of cytokines they release. They may also either increase or decrease inflammation, depending on the activating stimulus. Alveolar macrophages normally have a *suppressive* effect on lymphocyte function, but this may be impaired in asthma after allergen exposure. In patients with asthma, there is a reduced secretion of IL-10 (an antiinflammatory protein secreted by macrophages) in alveolar macrophages. Macrophages may therefore play an important antiinflammatory role by maintaining tolerance within the respiratory tract. There are subtypes of macrophages that perform different inflammatory, antiinflammatory, or phagocytic roles in airway disease; but at present, it is difficult to differentiate these subtypes in the human airway. There is evidence that alveolar macrophages show reduced phagocytosis of apoptotic cells and carbon particles in severe asthma so that inflammation does not resolve.[49,50]

## Dendritic Cells

Dendritic cells (DC) are specialized innate antigen presenting cells that have a unique ability to initiate and regulate cell mediated and humoral immune responses. DCs can be defined as any mononuclear phagocyte that can take up antigen, process it for presentation on major histocompatibility complex (MHC)-I or II, migrate to the nearest draining lymph node, and efficiently and effectively activate and polarize naïve T cells.[51] Subsequently, with the aid of costimulatory molecules (e.g., B7.1, B7.2, and CD40), they program the production of allergen-specific T cells. People with genetic defects resulting in a lack of DCs, or mice wherein DCs are experimentally depleted, suffer from severely impaired adaptive T and B cell responses. DCs reside beneath the pulmonary epithelium in the lung tissue, and are poised to encounter foreign material (allergen), infections, or tissue damage. They are aided by their ability to actively sample antigens in the airways via cellular extensions that protrude through the epithelial tight junctions.[52] Although their numbers are low in the lung, DCs are highly sensitive to their environment, expressing a variety of pattern recognition receptors (PRRs) including TLRs, C-type lectin receptors, and Nodlike receptors (NLRs). Through these receptors, they can sense a wide range of pathogens, microbes, or damage-associated molecules (DAMPs); these include bacterial, viral, fungal and protozoal pathogens, commensals and allergens, particles, and pollutants. Additionally, the pulmonary environment presents some unique features compared to other barrier sites, such as specific surfactants and mucins, which can influence DC activation and function.[53] Importantly, the combination of PRRs can tailor the developing immune response by directly influencing the activation and function of DCs. A number of DC subpopulations have been defined in the lungs including myeloid DCs (mDCs),[54] conventional DCs that initiate T-cell immunity and antibody production, and plasmacytoid DCs (pDCs)[55] that have an important role in antiviral immunity and immune tolerance.[56] DCs induce a T-lymphocyte–mediated immune response and therefore play a critical role in the development of asthma.[57] Increased numbers of mucosal DCs are present in asthma, and they have been identified in endobronchial biopsies, broncho-alveolar lavage, and induced sputum from patients with asthma. Animal studies have demonstrated that myeloid dendritic cells are critical to the development of T helper type 2 (Th2) cells and eosinophilia.

## Eosinophils

Eosinophils form an essential part of the innate immune response against parasitic helminths acting through the release of cytotoxic granule proteins. However, airway eosinophilic inflammation is also a central feature in allergic asthma. Allergen inhalation results in a marked increase in eosinophils in bronchoalveolar lavage fluid, and there is a correlation between eosinophil counts in peripheral blood and bronchial lavage in patients who are not receiving steroid treatment. Eosinophils develop from bone marrow precursors and are recruited to the lung via chemokines and cytokines.[58] Eosinophil recruitment initially involves adhesion of eosinophils to vascular endothelial cells in the airway circulation and then is followed by migration into the submucosa and activation. There have been extensive investigations of the role of individual adhesion molecules, cytokines, and mediators in orchestrating these responses. Adhesion of eosinophils involves the expression of specific glycoprotein molecules on the surface of eosinophils (integrins) and expression of such molecules as intercellular adhesion molecule-1 (ICAM-1) on vascular endothelial cells. The adhesion molecule very late antigen-4 (VLA4) expressed on eosinophils, which interacts with vascular cell adhesion molecule-1 (VCAM-1) and IL-4, increases its expression on endothelial cells. Granulocyte macrophage colony stimulating factor (GM-CSF) and IL-5 may be important for the survival of eosinophils in the airways and for “priming” eosinophils to exhibit enhanced responsiveness.

There are multiple mediators involved in the migration of eosinophils from the circulation to the surface of the airway. The most potent and selective agents appear to be chemokines (e.g., CCL5, CC11, CCL13, CCL24, and CCL26), which are expressed by epithelial cells. There appears to be a cooperative interaction between IL-5 and chemokines so that both are necessary for the eosinophilic response in the airway. Once recruited to the airway, eosinophils require the presence of various growth factors, of which GM-CSF and IL-5 appear to be the most important. In the absence of these growth factors, eosinophils undergo programed cell death (apoptosis).

After humanized monoclonal antibody to IL-5 is administered to asthmatic patients, there is a profound and prolonged reduction in circulating eosinophils and eosinophils recruited into the airway following allergen challenge.[59] However, there is no effect on the response to inhaled allergen and no change in lung function. Recent studies with highly selected patients with persistent sputum eosinophilia despite high doses of inhaled corticosteroids have shown a reduction in asthma attacks following treatment with anti-IL-5 antibody therapy.[60,61] The selective response in patients with a persistent eosinophilia underscores the importance of understanding the differing inflammatory processes in subgroups of patients with asthma rather than applying the same strategies to all patients (see Chapter 43).

## Neutrophils

In addition to physical barriers, such as the airway epithelium, neutrophils are part of the first line of immune defense. They can be found in the bloodstream, where they have a lifespan of 6–8 hours, and in tissue, where they can survive for up to 7 days.[62] They are the first cells of the immune system to migrate to a site of inflammation, where they play an important role in pathogen elimination and cytokine production. The mechanisms that neutrophils use for host defense include phagocytosis, degranulation, cytokine production, and the recently described production of neutrophil extracellular traps (NETs).[63] NETs were discovered in 1996 as a pathway of cellular death that was different from apoptosis and necrosis.[64] Neutrophil extracellular traps are DNA structures released due to chromatin decondensation and spreading, and they occupy three to five times the volume of condensed chromatin.[65] NETs arise from the release of granular and nuclear contents of neutrophils in the extracellular space in response to different classes of microorganisms, soluble factors, and host molecules.[66] Several proteins adhere to NETs, including histones and components of neutrophil granules with bactericidal activity such as elastase, myeloperoxidase, cathepsin G (CG), and lactoferrin. The detrimental effect of excessive NET release is particularly important to lung diseases, because NETs can expand in the pulmonary alveoli, causing lung injury. Massive NET formation has been reported in pulmonary diseases, including asthma, chronic obstructive pulmonary disease, cystic fibrosis, respiratory syncytial virus bronchiolitis, influenza, bacterial pneumonia, and tuberculosis. Thus, NET formation must be tightly regulated to avoid NET-mediated tissue damage. Recent approaches to target NETs in pulmonary diseases include DNA disintegration with recombinant human DNase, and neutralization of NET proteins with antihistone antibodies and protease inhibitors.

Neutrophils are the predominant inflammatory cells in patients with CF and chronic suppurative lung diseases such as PCD and bronchiectasis. Studies utilizing bronchoscopy to collect lower airway samples from very young children with CF have identified neutrophilic inflammation both with and without cultured bacterial pathogens.[67,68] These data suggest that inflammation may develop prior to chronic infection. However, studies using molecular genetic approaches to characterize the airway microbiome have shown numerous microbes present in the CF lung that are not readily cultured under standard conditions.[69] Whether such microbes are pathogenic or proinflammatory is uncertain,[70] but they can be found in very young children and may also help explain why neutrophilic airway inflammation is present when bacteria are not identified by traditional methods.[71] Nebulized hypertonic saline has been shown to improve mucus clearance in CF and impact positively upon pulmonary exacerbations, but there is also increasing evidence to suggest that hypertonic saline is beneficial through its antiinflammatory properties and its ability to reduce bacterial activity and biofilm formation.[72] The specific mechanisms involved include the downregulation of oxidative burst activity and adhesion molecule expression and the suppression of neutrophil degranulation of proteolytic enzymes. In addition, a potential pathogenic role of neutrophilic inflammation in both CF and non-CF bronchiectasis has been shown by interventional studies that have demonstrated improved lung function with the use of antiinflammatory agents such as the macrolide azithromycin, although the exact mechanisms of benefit of macrolides is unclear.[73–75]

In contrast to CF and non-CF bronchiectasis, the numbers and function of airway neutrophils in asthma remains uncertain. Although they are reported to be increased in severe asthma in adults, numbers in the airway lumen and lung parenchyma are not elevated in children with severe asthma.[76,77] However, a sub-group of children have increased intraepithelial neutrophils. Intriguingly, these patients have better lung function and asthma control, suggesting the neutrophils may be protective rather than pathogenic. The functional role of neutrophils in asthma has been further questioned by interventional studies that have shown little/no benefit of the antiinflammatory macrolide azithromycin either during infective exacerbations[78] or to prevent exacerbations.[79] Putative causes for airway neutrophilia in asthma are corticosteroid therapy, which inhibits neutrophil apoptosis, chronic infection with atypical organisms such as Chlamydia or Mycoplasma, exposure to passive smoking and other environmental pollutants, and gastroesophageal reflux and aspiration. However, it is still not clear whether neutrophils play a pathophysiologic role in the disease.

## T-Lymphocytes

T-lymphocytes play a very important role in coordinating the inflammatory response in asthma[80] through the release of specific patterns of cytokines, resulting in the recruitment and survival of eosinophils and in the maintenance of mast cells in the airways.[81] T-lymphocytes are coded to express a distinctive pattern of cytokines, which are similar to that described in the murine T helper 2 (Th2) type of T-lymphocytes, which characteristically express IL-4, IL-5, IL-9, and IL-13 (Fig. 7.5; see also Fig. 7.3). This programming of T-lymphocytes is presumably due to antigen-presenting cells, such as dendritic cells, which may migrate from the epithelium to regional lymph nodes or interact with lymphocytes resident in the airway mucosa. The naïve immune system is skewed to express the Th2 phenotype; data now indicate that children with atopy are more likely to retain this skewed phenotype than normal children. There is some evidence that early infections or exposure to endotoxins might promote Th1-mediated responses to predominate and that a lack of infection or a clean environment in childhood may favor Th2 cell expression and thus atopic diseases.[82] Indeed, the balance between Th1 cells and Th2 cells is thought to be determined by locally released cytokines, such as IL-12, which tip the balance in favor of Th1 cells, or IL-4 and IL-13, which favor the emergence of Th2 cells. There is accumulating evidence that a population of tissue resident memory cells (Trm) are long lived within the lung and facilitate development of T-cell responses upon reencounter with allergen. Although these Trm ensure efficient clearance of viruses, they may exacerbate allergic inflammation.[83] Regulatory T cells (Tregs) suppress the immune response through the secretion of inhibitory cytokines (e.g., IL-10 and TGF-β) (see Fig. 7.3, Chapter 43) and play an important role in immune regulation with suppression of Th1 responses; there is some evidence that Treg function may be defective in asthmatic patients.[84] Details of lymphoid cell responses in children with asthma, including the role of Th17 cells, T regulatory cells and the recently described innate lymphoid cells are discussed in Chapter 43.

**FIG. 7.5** T cell differentiation and cytokine production in pulmonary adaptive immunity following antigen presentation. The pulmonary antigen presenting cell *(APC),* or dendritic cell, presents antigen via MHC class II to the naïve T cell, and under the influence of the cytokines that have been secreted, the naïve T cell is converted to a T helper cell, which secretes further cytokines. In allergy, these are IL-4, IL-5, and IL-13 from Th2 cells; in infection, Th1 cells secrete IFN-γ and TNF-α; and in both allergy and infection, Th17 cells secrete IL-6, IL-17, or IL-22. *CTLA4*, Cytotoxic T-lymphocyte-associated protein 4; *IL,* interleukin; *IFN,* interferon; *MHC,* major histocompatibility complex; *TCR*, T cell receptor; *TGF,* transforming growth factor; *TNF,* tumor necrosis factor.

Patients with CF are known to have an imbalance in the composition of lymphocytic inflammation as well as the presence of neutrophilia. Interestingly, the neutrophilia seems confined to the airway lumen, while the infiltrate in the airway wall in children with CF is predominantly lymphocytic,[85] specifically being composed of IL-17+ CD4+ (Th17) cells and gamma delta T cells.[86] A Th2/Th17 skewed inflammatory response has been associated with increased risk for *Pseudomonas aeruginosa* infection.[87] Moreover, the numbers of regulatory T cells (CD4+CD25+FoxP3+) in peripheral blood are reduced in patients with CF with chronic *P. aeruginosa* infection and the reduction correlates with impaired lung function,[88] suggesting immune manipulation of Tregs to try and dampen proinflammatory responses might be a therapeutic strategy in patients with established CF lung disease.

## Innate Lymphoid Cells

Innate lymphoid cells (ILCs) are classified into three groups based on their transcription factors and cytokine production patterns, which mirror helper T-cell subsets. Unlike T cells and B cells, ILCs do not have antigen receptors. They respond to innate factors released by the bronchial epithelium, such as cytokines and alarmins, including IL-33, IL-25, and thymic stromal lymphopoietin (TSLP). ILCs produce multiple proinflammatory and immunoregulatory cytokines for the induction and regulation of inflammation.[89] These cells are specifically produced at mucosal surfaces and thus are important in airway inflammation. The role of ILCs, and more specifically type 2 ILCs, in the pathogenesis of allergic airways diseases has been extensively investigated over the last decade,[90] and the evidence for their involvement in pediatric severe asthma has been discussed in Chapter 43. However, the role of ILCs in infectious and nonallergic airway inflammatory diseases remains largely unknown. Specifically, the role of ILC1 cells, which produce IFN$\gamma$ and may be important in viral infections and ILC3 cells, which produce IL-17 and may be important in suppurative lung disease such as cystic fibrosis, are unknown.

## B-Lymphocytes

In allergic diseases, B-lymphocytes secrete IgE, and the factors regulating IgE secretion are now much better understood.[91] IL-4 is crucial in switching B cells to IgE production, and CD40 on T cells is an important accessory molecule that signals through interaction with CD40-ligand on B cells. There is increasing evidence for local production of IgE, even in patients with intrinsic asthma.[92,93] For example, a recent clinical trial has shown treatment of adult patients with nonatopic asthma with the anti-IgE antibody omalizumab reduced bronchial mucosal IgE$^+$ mast cells and improved lung function despite withdrawal of conventional therapy.[94]

## Basophils

Functionally, basophils are closely related to mast cells. Both cell types express the high-affinity IgE receptor (FcεRI) and rapidly release preformed mediators from intracellular stores upon IgE-mediated activation. However, in contrast to mast cells, basophils mature in the bone marrow and have a lifespan of only 2–3 days.[95] The exact role and importance of basophils in asthma is uncertain, as these cells have been difficult to detect by immunocytochemistry and most studies investigating the mechanistic role of these cells are limited to experimental murine models. However, it appears that basophils have both proinflammatory and antiinflammatory actions. They recruit effector cells such as Th2 cells, ILC2s, eosinophils, and inflammatory macrophages to the site of inflammation; and they are also able to limit inflammation by release of amphiregulin, induction of alternative activation of macrophages, and orchestration of an antiinflammatory Th2 milieu.[96] Using a basophil-specific marker, a slight increase in basophils has been documented in the airways of asthmatic patients, with an increased number after allergen challenge. However, these cells are far outnumbered by eosinophils (approximately 10 : 1), and their functional role is unknown.[97] There is also an increase in the numbers of basophils, as well as mast cells, in induced sputum after allergen challenge.

# Structural Cells as Sources of Mediators

Structural cells of the airways, including epithelial cells, endothelial cells, fibroblasts, and even airway smooth muscle cells,[98] may be an important source of inflammatory mediators, such as cytokines and lipid mediators in asthma and CF. Indeed, because structural cells far outnumber inflammatory cells in the airway, they may become the major source of mediators driving chronic airway inflammation. Epithelial cells play a key role as immunologically active cells in translating inhaled environmental signals into an airway inflammatory response and they are at the center of the inception and propagation of immune responses in asthma (Fig. 7.6).[99–101]

Epithelial cells may also play an important role in CF by driving the neutrophilic inflammatory response through the release of CXCL1 and CXCL8. Airway epithelial cells may also be important in driving the structural changes that occur in chronic airway inflammation through the release of growth factors.[102] Epithelial cell integrity might also be an important factor in denying allergens exposure to the immune system, and an increasing number of asthma susceptibility genes are expressed in the airway epithelium.[103–105] The critical role of the airway epithelium in orchestrating the pathophysiology of asthma has been discussed in detail in Chapter 43.

**FIG. 7.6** The airway epithelium at the center of the immune response in asthma. The airway epithelium forms both a barrier to prevent the entry of foreign particles and is immunologically active. There is continued movement of immune cells through the epithelium that allows detection of foreign particles and the development of an appropriate immune response in health. However, in asthma, the barrier becomes "leaky" and particles move from the lumen through to the submucosa with the induction of a type 2

inflammatory response and secretion of mediators and a parallel impact on the submucosal structural cells such as the airway smooth muscle, which also actively secretes inflammatory cytokines.

## Inflammatory Mediators

Many different mediators have been implicated in asthma, and they may have a variety of effects on the airway, which accounts for all the pathological features of asthma (Fig. 7.7).[106] Although less is known about the mediators of CF,[107] it is becoming clear that they differ from those implicated in asthma. Because each mediator has many effects, the role of individual mediators in the pathophysiology of airway inflammatory disease is not yet clear. The multiplicity and redundancy of effects of mediators make it unlikely that preventing the synthesis or action of a *single* mediator will have a major impact in the therapy of these diseases. However, some mediators may play a more important role if they are upstream in the inflammatory process. The effects of single mediators can only be evaluated with specific receptor antagonists or mediator synthesis inhibitors.

### Cytokines

Cytokines play a significant role in orchestrating the type of inflammatory response seen in airways diseases (Fig. 7.8; see also Fig. 7.3).[108] Many cytokines currently form the target for the development of new asthma therapies.[109] Multiple inflammatory cells (macrophages, mast cells, eosinophils, and lymphoid cells) and airway structural cells are capable of synthesizing and releasing cytokines. While inflammatory mediators such as histamine and leukotrienes may be important in the acute and subacute inflammatory responses and in exacerbations of asthma, it is likely that cytokines play a dominant role in maintaining chronic inflammation in airway diseases. The cytokines that appear to be of importance in asthma include the type 2, or Th2 cytokines that are secreted by T-lymphocytes and innate lymphoid cells. These include IL-4, IL-5, and IL-13. Details of the cellular source, functional role, and potential of these cytokines as therapeutic targets in asthma are summarized in Chapter 43. Other proinflammatory cytokines (e.g., IL-1β, IL-6, TNF-α, and GM-CSF) are released from a variety of cells, including macrophages, epithelial cells, T helper 1, and T helper 17 cells (see Fig. 7.8), and may be important in amplifying the inflammatory response. TNF-α may be an amplifying mediator in asthma and is produced in increased amounts in airways of patients with severe asthma. However, blocking TNF-α with a potent antibody had no clinical benefit in patients with severe asthma, and it also led to an increased risk of infections and cancers.[110] TNF-α and IL-1β both activate the proinflammatory transcription factors—nuclear factor-κB (NF-κB) and activator protein-1 (AP-1)—which then switch on many inflammatory genes in the asthmatic airway.

Thymic stromal lymphopoietin (TSLP) shows a marked increase in expression in airway epithelium and mast cells of asthmatic patients.[111] TSLP appears to play a key role in programing airway dendritic cells to release CCL17 and CCL22 to attract Th2 cells (Fig. 7.9).[112] A clinical trial of an anti-TSLP antibody in adults with mild allergic asthma showed reduced bronchoconstriction and reduced airway eosinophilic inflammation after an acute allergen challenge in the patients who received the active drug,[113] suggesting that this may be a novel target following an acute allergen induced exacerbation of asthma, but this was a small trial that requires further confirmation.

## Lipid Mediators

The cysteinyl-leukotrienes, $LTC_4$, $LTD_4$, and $LTE_4$, are potent constrictors of human airways and may also increase AHR. Leukotriene antagonists have some bronchodilator and antiinflammatory effects but are much less effective than inhaled corticosteroids in the management of childhood asthma.[114] Platelet-activating factor (PAF) is a potent inflammatory mediator that mimics many of the features of asthma, including eosinophil recruitment and activation and induction of AHR; yet even potent PAF antagonists, such as dominant, do not control asthma symptoms, at least in chronic asthma. Prostaglandins (PG) have potent effects on airway function, and there is increased expression of the inducible form of cyclooxygenase (COX-2) in asthmatic airways; however, inhibition of their synthesis with COX inhibitors, such as aspirin or ibuprofen, has no effect in most patients. Prostaglandin $D_2$ is a bronchoconstrictor prostaglandin produced predominantly by mast cells; it also activates a novel chemoattractant receptor termed *chemoattractant receptor of Th2 cells* (CRTh2) or *$DP_2$-receptor,* which is expressed on Th2 cells and eosinophils and mediates chemotaxis of these cell types. It may provide a link between mast cell activation and allergic inflammation. Several oral CRTh2/$DP_2$ antagonists are now in clinical development.[115]

Lipid mediators are also crucial for the resolution of inflammation. Resolvins and protectins are a relatively newly described class of lipids that are thought to be important for the down regulation and resolution of inflammation, thereby leading to restitution of immune homeostasis. Mechanistic data from experimental models show that resolvins can promote clearance of inflammatory cells after allergen exposure, resulting in improved lung function.[14] They have also been described in adult asthmatic patients after allergen challenge.[116]

## Chemokines

Both cytokines and chemokines are small proteins made by cells in the immune system. They are important in the production and growth of immune cells and in regulating responses to inflammation and wound healing. The term “cytokines” encompasses all signaling molecules while chemokines are specific cytokines that function by attracting cells to sites of infection/inflammation. Chemokines are defined either according to the pattern of cysteine residues in the ligands (CC, CXC, C, and CX3C) or their function and pattern of expression (homeostatic and inflammatory chemokines).[117] Many chemokines are involved in the recruitment of inflammatory cells to the airways.[34] Over 50 different chemokines are now recognized, and they activate more than 20 different surface receptors. Chemokine receptors belong to the seven-transmembrane receptor superfamily of G-protein–coupled receptors; this makes it possible to find small molecule inhibitors, which has not been possible for classical cytokine receptors.[118] Some chemokine receptors appear to be selective for single chemokines, whereas others are promiscuous and mediate the effects of several related chemokines. Chemokines appear to act in sequence in determining the final inflammatory response, and so inhibitors may be more or less effective depending on the kinetics of the response. T-cell migration in response to G-protein coupled receptor (GPCR)-coupled chemokine receptors plays a prominent role in navigating distinct T-cell subsets at different stages of the immune response to their intended destinations at sites of infection and inflammation (Fig. 7.10).

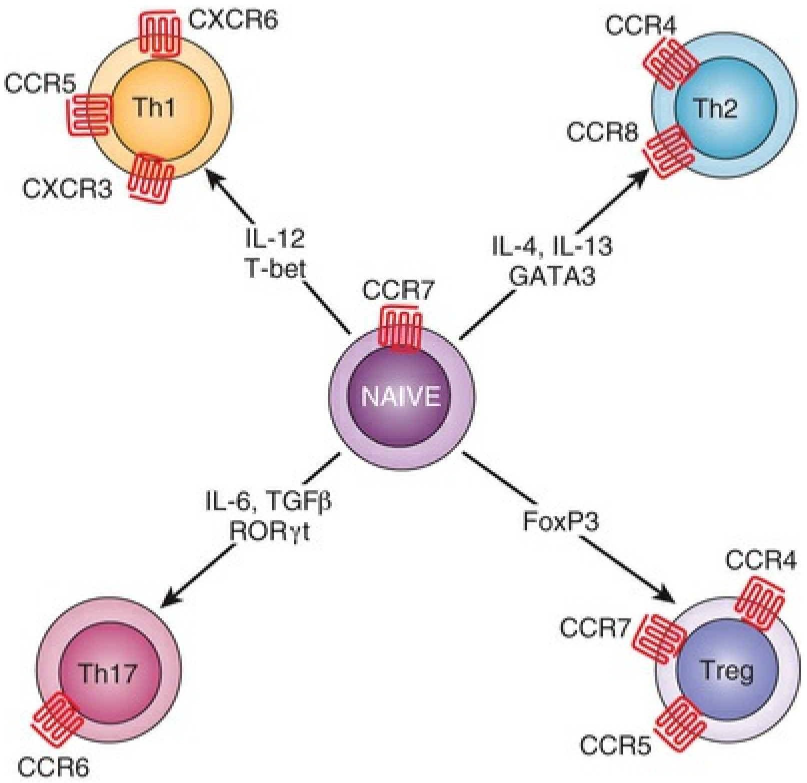

**FIG. 7.10** Chemokine and cytokine interactions on T lymphocytes. Chemokine receptors are g-protein coupled receptors (GPCR) that span the cell membrane of T lymphocytes, and binding of cytokines to these receptors defines the functional phenotype of the T lymphocyte subset. *CCR,* Chemokine receptor; *IL,* interleukin; *TGF,* transforming growth factor.

Several chemokines, including CCL5, CC11, CCL13, CCL24, and CCL26, activate a common receptor on eosinophils termed *CCR3*. Increased expression in the airways of asthmatic patients is correlated with increased AHR. CCR4 chemokines are selectively expressed on Th2 cells and are activated by the CCL17 and CCL22 chemokines. Epithelial cells of patients with asthma express CCL22, which may then recruit Th2 cells, resulting in coordinated eosinophilic inflammation.

CXC chemokines are involved in the recruitment of neutrophils. CXCL1 and CXCL8 play an important role in neutrophilic inflammation in severe asthma and CF.

## Oxidative Stress

As in all inflammatory diseases, there is increased oxidative stress associated with pulmonary inflammation, as activated inflammatory cells, such as macrophages, neutrophils, and eosinophils, produce reactive oxygen species. Evidence for increased oxidative stress in asthma and CF is provided by the increased concentrations of 8-isoprostane (a product of oxidized arachidonic acid) in exhaled breath condensates and increased ethane (a product of oxidative lipid peroxidation) in exhaled breath of asthmatic patients.[119,120] Increased oxidative stress is correlated with disease severity and may amplify the inflammatory response and reduce responsiveness to corticosteroids, particularly in severe disease and during exacerbations.

## Nitric Oxide

Nitric oxide (NO) is generated from various resident and inflammatory cells in the human airway when L-arginine undergoes the process of oxidation by one of three NO synthase (NOS) isoenzymes: endothelial NOS, inducible NOS, and neuronal NOS. The physiologic roles that NO has in the respiratory system are numerous and include neurotransmission, vasodilatation, bronchodilation, and immune augmentation. At the onset of an asthma attack, an enhanced production of NO strongly correlates with increased inducible NOS activity, whereas endothelial NOS and neuronal NOS primarily regulate normal metabolic functions in the central and peripheral airways.[121] During allergic inflammatory responses, NO and superoxide form peroxynitrite, which has deleterious effects in the respiratory tract. The inducible form of NOS (iNOS) shows increased expression, particularly in the airway epithelial cells and macrophages of asthmatic airways. Although the role of NO in the asthmatic airway is not fully understood, the levels of NO are often increased in asthma.[122] This elevation is thought, in part, to reflect increased inducible NOS activity in the airways. Although the cellular source of NO within the lung is not known, inferences based on mathematical models suggest that it is the large airways that are the source of NO; in severe asthma, there is evidence that small airways also produce it.[123] Extended NO analysis is a promising tool in different diseases such as asthma where NO metabolism is altered. One single exhalation cannot give insight to the NO production in the whole respiratory system; the use of multiple exhalation flows has therefore been used to give the alveolar levels (C(A)NO), the airway wall concentration (C(aw)NO), and the diffusion rate of NO (D(aw)NO).[124] Low levels of bronchial NO flux (J'(aw)NO) are seen in cystic fibrosis, PCD and in smoking subjects. However, more studies are needed to evaluate the clinical usefulness of the extended NO analysis; this has been done in systemic sclerosis where a cutoff value has been identified, predicting pulmonary function deterioration.[125,126]

## Growth Factors

Many growth factors are released from inflammatory and structural cells in airway diseases; these may play a critical role in the structural changes that occur in chronic inflammation, including fibrosis, airway smooth muscle thickening, angiogenesis, and mucous hyperplasia. While the role of individual mediators is not yet established, there is evidence for increased expression of TGF-β (a mediator associated with fibrosis), vascular-endothelial growth factor (a mediator associated with angiogenesis), and epidermal growth factor (a mediator that induces mucous hyperplasia and expression of mucin genes) (Fig. 7.11). A key pathological component of asthma is airway remodeling, and it is likely that several growth factors are important in mediating the development of these structural changes; however, to date, there are no specific therapeutics that target airway remodeling.

## Neural Mechanisms

Neural mechanisms may play an important role in the inflammatory response of airways. Neural reflexes may be activated by inflammatory signals, resulting in reflex bronchoconstriction; and airway nerves may release neurotransmitters, particularly neuropeptides, that have inflammatory effects.[127] There is a close interaction between nerves and inflammatory cells in allergic inflammation, as inflammatory mediators activate and modulate neurotransmission, whereas neurotransmitters may modulate the allergic inflammatory response. Inflammatory mediators may act on various prejunctional receptors on airway nerves to modulate the release of neurotransmitters. Inflammatory mediators also activate sensory nerves, resulting in reflex cholinergic bronchoconstriction or release of inflammatory neuropeptides (Fig. 7.12). There is particular interest in the role of neural mechanisms in animal models and human disease caused by respiratory syncytial virus.[128–130]

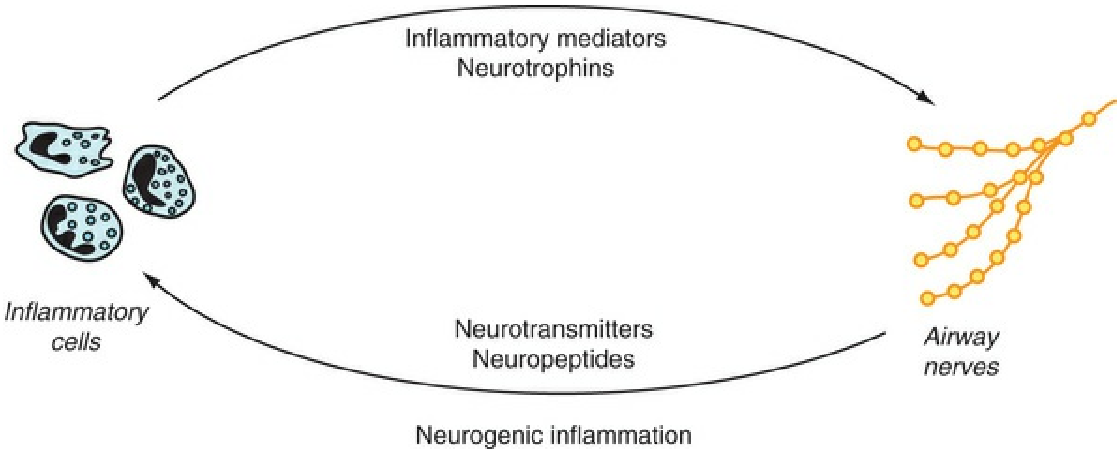

**FIG. 7.12** Two-way interaction between inflammation and neural control of the airways.

Inflammatory products may also sensitize sensory nerve endings in the airway epithelium so that the nerves become hyperalgesic. Hyperalgesia and pain *(dolor)* are cardinal signs of inflammation; and in the asthmatic airway, hyperalgesia may mediate cough and chest tightness, which are characteristic symptoms of asthma. The precise mechanisms are not yet certain, but mediators such as prostaglandins, certain cytokines, and neurotrophins may be important. Neurotrophins, which are released by various cell types in peripheral tissues, may cause proliferation and sensitization of airway sensory nerves.[131] Neurotrophins, such as nerve growth factor (NGF), may be released from inflammatory and structural cells in asthmatic airways and then stimulate the increased synthesis of neuropeptides (e.g., substance P [SP]) in airway sensory nerves, as well as sensitizing nerve endings in the airways. NGF released from human airway epithelial cells after exposure to inflammatory stimuli may play an important role in mediating AHR in asthma.

Airway nerves may also release neurotransmitters that have inflammatory effects. Thus, neuropeptides such as SP, neurokinin A, and calcitonin-gene–related peptide may be released from sensitized inflammatory nerves in the airways, increasing and extending the ongoing inflammatory response in asthma and other types of chronic airway inflammation.[132]

## Transcription Factors

The chronic inflammation of asthma and CF is due to increased expression of multiple inflammatory proteins (i.e., cytokines, enzymes, receptors, adhesion molecules). In many cases, these inflammatory proteins are induced by transcription factors, DNA binding factors that increase the transcription of selected target genes (Fig. 7.13). One transcription factor that may play a critical role in asthma is NF-κB, which can be activated in asthmatic airways, particularly in epithelial cells and macrophages. NF-κB regulates the expression of several key genes that are overexpressed in asthmatic and CF airways, including proinflammatory cytokines (IL-1β, TNF-$\alpha$, GM-CSF), chemokines (IL-8, Regulated on Activation, Normal T Cell Expressed and Secreted [RANTES], macrophage inflammatory protein [MIP]-1$\alpha$, eotaxin), adhesion molecules (ICAM-1, VCAM-1), and inflammatory enzymes (cyclooxygenase-2, iNOS).[133] Many other transcription factors are involved in the abnormal expression of inflammatory genes in asthma, and there is growing evidence that there may be a common mechanism that involves activation of coactivator molecules at the start site of transcription of these genes. They are activated by transcription factors that induce acetylation of core histones around which DNA is wound in the chromosome. Local unwinding of DNA opens the chromatin structure and allows RNA polymerase and other transcription factors to bind, thus switching on gene transcription.[134]

**FIG. 7.13** Proinflammatory transcription factors in asthma. Transcription factors play a key role in amplifying and perpetuating the inflammatory response in asthma. Transcription factors, including nuclear factor kappa-B (*NF*-κB), activator protein-1 (*AP*-1), and signal transduction-activated transcription factors *(STATs)*, are activated by inflammatory stimuli and increase the expression of multiple inflammatory genes.

Transcription factors play a critical role in determining the balance between Th1 and Th2 cells. The transcription factor GATA-3 determines the differentiation of Th2 cells and the expression of Th2 cytokines, and it shows increased expression in asthmatic patients.[135] Increasing numbers of therapeutics that target specific transcription factors are being developed, especially for asthma since these factors are upstream of the cytokines released from T helper cells. However, as they are intracellular factors, they cannot be targeted by antibodies. GATA-3 is considered the master regulator of type 2 immunity and therefore an ideal target for asthma. Development of a GATA-3-specific DNAzyme, a molecule class that combines the specificity of antisense molecules with an inherent RNA-cleaving enzymatic activity, has recently moved from preclinical development toward a proof-of-concept clinical study.[136] The differentiation of Th1 cells is regulated by the transcription factor T-bet, and the differentiation of Th17 cells is regulated by Ror-γT.[137,138]

## Antiinflammatory Mechanisms

Although most emphasis has been placed on inflammatory mechanisms, there may be important antiinflammatory mechanisms that may be defective in asthma, resulting in increased inflammatory responses in the airways.[139] Endogenous cortisol may be important as a regulator of the allergic inflammatory response, and nocturnal exacerbation of asthma may be related to the circadian fall in plasma cortisol. The blockade of endogenous cortisol secretion by metyrapone results in an increase in the late response to allergen in the skin. Cortisol is converted to the inactive cortisone metabolite by the enzyme 11β-hydroxysteroid dehydrogenase, which is expressed in airway tissues. The molecular apparatus that underpins circadian variations, controlled by so called 'clock' genes, has recently been characterized. Clock genes control circadian rhythms both centrally, in the brain and peripherally, within every organ of the body. It has therefore been proposed that the peripheral lung clock and the peripheral immune clock might relate to both the pathogenesis and treatment of asthma.[140]

Various cytokines have antiinflammatory actions. IL-1 receptor antagonist (IL-1RA) inhibits the binding of IL-1 to its receptors and therefore has a potential antiinflammatory capability in asthma, and it is reported to be effective in an animal model of asthma. IL-12 and IFN-γ enhance Th1 cells and inhibit Th2 cells. IL-12 promotes the differentiation and thus the suppression of Th2 cells, resulting in a reduction in eosinophilic inflammation, and its expression may be reduced in asthmatic airways.

IL-10, which was originally described as cytokine synthesis inhibitory factor, inhibits the expression of multiple inflammatory cytokines (TNF-α, IL-1β, GM-CSF) and chemokines, as well as inflammatory enzymes (iNOS, COX-2). There is evidence that IL-10 secretion and gene transcription are defective in macrophages and monocytes from asthmatic patients; this may lead to enhancement of inflammatory effects in asthma and may be a determinant of asthma severity.[141] IL-10 secretion is lower in monocytes from patients with severe asthma compared to mild asthma, and there is an association between haplotypes associated with decreased production and severe asthma.

Another family of molecules of potential interest is the lung Kruppel-like transcription factor (LKLF) family of proteins. LKLF plays a pivotal role in maintenance of T-lymphocyte quiescence,[12] which this is of interest in view of our recent findings of increased T cells in the CF airway.[142] A recent manuscript showed that LKLF suppresses *P. aeruginosa*–induced activation of NF-κB and subsequent IL-8 release from airway cells, but, in turn, its expression was inhibited by the proinflammatory cytokine TNF-$\alpha$.[12] There was evidence that LKLF is abundantly present in normal small airway human tissue sections, but the signal lessens as inflammation worsens, and the presence of activated human neutrophils "switches off" LKLF in airway epithelial cells. This suggests a counter-inflammatory role for LKLF in airway epithelium and provides evidence for cytokine regulation of LKLF in a TNF-$\alpha$–dependent fashion. LKLF downregulation may be a mechanism by which the presence of neutrophil-secreted cytokines in the airway lumen contributes to the continuous activation of airway epithelium in CF lung disease.

Lipoxins (LX) are antiinflammatory lipid mediators that modulate neutrophilic inflammation.[13] Reduced $LXA_4$ was first described in broncho-alveolar lavage fluid (BALF) from CF patients; in a mouse model, exogenous $LXA_4$ was shown to abrogate inflammation and infection and reduce disease severity.[143] Recent studies have further elucidated the regulation of this mediator.[14] Resolvin E1 (RvE1), which is a potent inhibitor of neutrophil transmigration across epithelial and endothelial barriers, has been shown to promote the resolution of airway inflammation by suppressing IL-23 and IL-6 production in the lung. This is of particular interest, given that IL-23 promotes the survival of $T_H$-17 cells in the airway.[144] These cells secrete IL-17A, which has been linked to the pathogenesis of a number of inflammatory diseases,[145] and has been found in BALF from children with CF.[146] Furthermore, administration of antibodies to IFN-$\gamma$ leads to increased BALF leukocytosis, which was abrogated by coadministration of RvE.[147]

So far, there is little, if any, evidence for a role of this axis in CF or other pediatric inflammatory lung diseases.

The docosohexanoic acid prostaglandin D (PD)1-derived mediator is one of the arachidonic acid–derived family of mediators that terminates inflammation, along with $LXA_4$ and its epimer aspirin-triggered $LXA_4$, and RvE1 (see earlier, derived from eicosopentanoic acid). A murine peritonitis model was used to demonstrate that inhibition of COX-2 or lipoxygenases leads to a defect of resolution of inflammation, which could be rescued by RvE1, PD1, or an aspirin-triggered $LPX_4$ analog.[148] No airway data have been reported, but this is another potential mechanism of resolution of inflammation that merits further investigation.

Other mediators may also have antiinflammatory and immunosuppressive effects. $PGE_2$ has inhibitory effects on macrophages, epithelial cells, and eosinophils; and exogenous $PGE_2$ inhibits allergen-induced airway responses. In addition, its endogenous generation may account for the refractory period after exercise challenge. However, it is unlikely that endogenous $PGE_2$ is important in most asthmatics, since nonselective COX-2 inhibitors only worsen asthma in a minority of patients (aspirin-induced asthma). Several other lipid mediators, including lipoxins, resolvins, and protectins, promote resolution of inflammation and may be reduced in asthma patients.[116]

# Direct Measurements of Airway Inflammation

There are far fewer bronchoscopic studies in children than in adults. This in part relates to ethics; any invasive procedure must be clinically indicated and of direct benefit to the individual child. Neither parents nor children can consent to an invasive procedure that is of no direct benefit to the child. It has been shown that bronchoscopy, bronchoalveolar lavage, and endobronchial biopsy are safe in school-aged children with severe asthma, preschool children with severe wheezing, and children of all ages with cystic fibrosis when performed carefully by experienced personnel.[149–152] It is ethical to take additional samples for research purposes at the time of a clinically indicated bronchoscopy if the Institutional Review Board approves the procedure, the parents give informed consent, and the child gives age-appropriate assent.[153] The main problem with pediatric bronchoscopic studies is that they are invariably cross-sectional, because serial bronchoscopies are rarely, if ever, appropriate in children. Other problems include the lack of milder asthmatics, since bronchoscopy is rarely indicated in these children, and the lack of true normal controls, since there is no nonrespiratory indication for a bronchoscopy. This last issue is addressed by studying children with upper airway disease; hemoptysis, for which no cause is found; or chronic cough unrelated to asthma. However, none of these controls is completely suitable. An alternative approach, which is also completely ethical with the previous caveats, is to do a blind nonbronchoscopic lavage and bronchial brushings in children who are intubated for routine pediatric surgery.[154,155] This is the only way that large numbers of normal or mildly asthmatic children can be studied.

There are several advantages of lower airway samples that are obtained directly by bronchoscopy: ability to obtain endobronchial biopsies (Fig. 7.14), which are the only way of assessing airway wall structural changes; no current samples obtained noninvasively, or even nonbronchoscopically will allow an assessment of remodeling. This is important, as it is increasingly recognized that the structural airway cells such as smooth muscle, vessels, and collagen have key immunological as well as functional roles in airways diseases. In addition, we know that the pattern of inflammation in the airway wall may be very different to that in the airway lumen, and importantly, the specific pattern of inflammation within airway wall structures may have functional implications. Examples of this are the presence of mast cells within airway smooth muscle as a characteristic feature of AHR in asthma[156] and the presence of neutrophils in the epithelium as a sub-phenotype of severe childhood asthma.[77] However, nonbronchoscopic sampling does offer the opportunity to obtain epithelial cells that can be cultured in vitro and stimulated with allergen, infection, or pollutants to investigate altered function in disease compared to controls. More recently, complex and realistic cultures that have an interface with basal endothelial cells, an apical airway lumen, and cocultures with leukocytes, representing a "lung on a chip" have been developed; and these represent significant advances for investigation of "in vivo" responses more closely using "in vitro" techniques (Fig. 7.15).[157–160]

**FIG. 7.15** Complex epithelial *in vitro* culture techniques to allow optimal assessments of airway cell function. The culture of cells at an air-liquid interface and the addition of a microfluidic chamber allow dynamic

movement to mimic blood flow, and the addition of inflammatory cells with epithelial cells allows optimal reflection of the dynamics of the airways and an opportunity to investigate mechanisms in vitro.

In addition to a difference between inflammatory cell patterns in the airway wall and airway lumen, it is known that inflammation may be very different in the upper compared to the lower airways, and upper airway samples (which can be obtained noninvasively) do not reflect the lower airways. Therefore bronchoalveolar lavage samples are important, as they can be used to obtain both inflammatory cells, which can be phenotyped and quantified using cytology (Fig. 7.16) or flow cytometry, and the supernatants can be used to measure inflammatory cytokines. However, there has always been a question relating to the reliability of mediators measured in broncho-alveolar lavage (BAL) because of the variability that may be introduced by dilution of the lavage fluid. An important advance in this area has been the recent introduction of techniques to sample the mucosal lining fluid of the airways directly using absorptive materials, such as a synthetic absorptive matrix.[161] This technique allows the collection of concentrated mucosal lining fluid and, using multiplex cytokine assays that allow the measurement of up to 20 cytokines from a small volume, enables a detailed characterization of airway inflammatory mediators.[162]

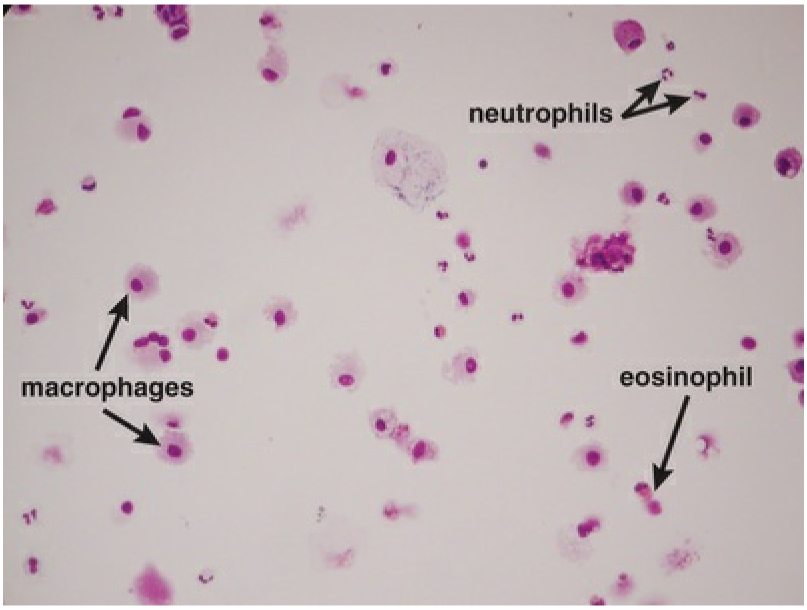

**FIG. 7.16** Broncho-alveolar lavage fluid cytospin showing airway luminal leukocytes.

This novel technique has been used to collect samples of the nasal mucosal lining fluid in infants to detect inflammatory mediators and has been used to collect bronchial mucosal lining fluid from adult patients with asthma, but it has not yet been used to compare inflammatory mediators from the upper and lower airways from the same patients. This information would be very helpful in determining the utility of nasal mucosal lining fluid as a surrogate for lower airway inflammation, with the advantage of being able to collect samples longitudinally from the same patient.

## Noninvasive Assessment of Airway Inflammation

Inflammation plays a key role in the pathophysiology of airway diseases, and suppression of this inflammation is a major aim of therapy. This implies that the degree of inflammation should be assessed during clinical management,[163] while physiologic measurements, such as spirometry, only reflect inflammation indirectly. Furthermore, spirometry is a notoriously poor asthma endpoint in children,[164–166] and treatment with bronchodilators makes changes difficult to interpret. Direct measurement of inflammation by bronchial biopsy or bronchoalveolar lavage is valuable in research studies, but it is clearly inappropriate for routine assessment and for repeated measurements, especially in children. This means that less invasive procedures for assessing airway inflammation need to be devised.

The characteristics of the ideal "inflammometer" are shown in Table 7.1. Unfortunately, no such instrument exists. There are two broad reasons for wishing to measure airway inflammation: to study the mechanisms of disease and as a clinical tool to monitor treatment in an individual. Unfortunately, the two are frequently confused. The finding that levels of a mediator are statistically significantly different between groups may lead to valuable pathophysiologic insights, but if the overlap between asthma and normal groups is considerable, measuring the mediator is likely to be of little value as a monitoring tool in clinical practice. This is illustrated by measurements of exhaled and nasal NO in PCD; exhaled nasal NO is lower in PCD than in normal groups, but the overlap means that it cannot be used as a diagnostic tool; on the other hand, a low nasal NO almost completely differentiated PCD from normal.[167] Biomarkers for asthma have been identified from a variety of sources, including airway, exhaled breath, and blood. Biomarkers from exhaled breath include fractional exhaled NO, and the measurement of which can help identify patients most likely to benefit from inhaled corticosteroids and targeted antiimmunoglobulin E therapy. Biomarkers measured in blood are relatively noninvasive and technically more straightforward than those measured from exhaled breath or directly from the airway.[168] The use of biomarkers can therefore potentially help to identify patients and avoid inappropriate therapies; if used correctly, it may allow the development of an individualized approach to treatment.

## Table 7.1

**Characteristics of the Ideal "Inflammometer"**

| |

| Cheap |
| Easy to maintain and calibrate |
| Completely noninvasive |
| Easy to use, no cooperation needed |
| Directly measures all relevant aspects of inflammation |

Provides rapid availability of answers
Evidence of beneficial clinical outcomes
Provides reliable longitudinal assessments

## Induced Sputum

Sputum may be induced by nebulized hypertonic saline (3.5% or 7%) for analysis of inflammatory cells and mediators. This technique has been applied successfully to children; however, it is difficult to use in clinical practice, and up to 25% of children do not produce a useable sample.[169] However, sputum induction can be performed safely in children with severe asthma.[170] More recently, the technique has been adapted for use in younger, preschool children. Although sputum induction can be performed safely and repeatedly in preschool children, the samples can only reliably be used to assess airway infection and not inflammation.[171] In addition, the procedure can be uncomfortable and requires significant technical expertise in terms of reliable processing and analysis. Sputum induction has proven to be a useful research technique in investigating airway inflammation in children. Initially, samples were assessed by simple cytology, but more recently, it has been shown that detailed inflammatory phenotyping can be undertaken using flow cytometry, and even rare populations such as innate lymphoid cells can be quantified.[172] Sputum measures proximal luminal inflammation but relates poorly to airway wall pathology and distal inflammatory changes. One study showed that the absence of eosinophils in induced sputum was predictive of a successful taper of inhaled steroids.[173] Another study[174] showed that a strategy of adjusting treatment to try to normalize induced sputum eosinophils measured every 3 months in children with severe asthma was not beneficial compared with a standard strategy. In addition, a *post hoc* analysis showed a reduction in exacerbations in the month immediately following the measurement.[174] Currently, there is insufficient evidence to recommend the routine use of induced sputum to assess airway inflammation in clinical practice because of the technical issues involved in obtaining samples in children and the lack of studies showing improved outcome.[175]

## Peripheral Blood

The increasing use of monoclonal antibodies to treat patients with eosinophilic asthma, specifically, anti-IL-5 antibody has shown the potential of peripheral blood eosinophils as a noninvasive surrogate for airway inflammation. However, this has only been shown convincingly in adult studies, since clinical trials with the antibody have only been undertaken in adult patients. However, it is apparent, that a blood eosinophil count >0.3 × $10^9$ eosinophils/L is considered elevated in the context of asthma and has been used as a marker to define eosinophilic asthma, which would be eligible for a trial of anti-IL-5 antibody therapy. The cutoff for blood eosinophils that corresponds to significant airway eosinophilia remains uncertain in school-aged children with severe asthma. When airway inflammation was compared to blood eosinophil levels in children with severe therapy resistant asthma who had been shown to be adherent to their maintenance high-dose inhaled steroids, the majority of children had a normal age-appropriate blood eosinophil count (<0.1 × $10^9$ eosinophils/L) despite having a persistent airway eosinophilia.[176] However, the cutoff for high blood eosinophils is likely to be lower when patients are taking high dose inhaled steroids, and this value and its potential utility as a biomarker to direct therapy in children is yet to be determined. It is possible that peripheral blood eosinophils are more useful as a noninvasive biomarker to guide the utility of inhaled steroids in preschool children with wheeze in whom there is a good correlation between BAL and blood eosinophils.[171] In addition, a recent clinical trial showed that phenotyping with aeroallergen sensitization and blood eosinophils is useful for guiding treatment selection in preschool wheeze.[177]

## Exhaled Gases

There has been considerable progress in the measurement of exhaled gases that may reflect the inflammatory process in the airways.[178] This technique is technically simple and is feasible, even in young children; and repeated measurements are possible and achievable in patients with severe disease.

## Exhaled Nitric Oxide

The most progress has been made with NO, which can be detected in exhaled breath by chemiluminescence analyzers. The concentration of NO is increased in the exhaled breath of children (including infants) with asthma and decreases with inhaled corticosteroid therapy.[179] Recent evidence indicates that FeNO identifies T-helper cell type 2 (Th2)–mediated airway inflammation with a high positive and negative predictive value for identifying corticosteroid responsive airway inflammation.[180] In addition, using multiple flows, it is possible to partition exhaled NO into central and peripheral fractions; and this provides information about inflammation in central and peripheral airways.[181] Exhaled NO is correlated with other markers of inflammation such as eosinophils in induced sputum and AHR in children; however, the relationship is not a particularly close one. The correlation between NO and airway eosinophilia is closest in steroid-naïve children (the group in whom it is least likely to be useful). Longitudinal studies[174] show that even in the same individual, the relationship between NO and sputum eosinophilia varies over time, with a high NO sometimes seen with a normal sputum eosinophil count, and vice versa.

There is some evidence that NO measurement may be useful in pediatric asthma. It may predict exacerbations in pollen-sensitive asthma[182] and may be helpful in supporting a diagnosis in steroid naïve patients. Two recent studies showed no evidence of benefit in adding exhaled NO to standard monitoring.[183,184] This probably indicates that, if basic management is optimized, most children respond so well to low to moderate doses of asthma therapy that there is little opportunity to demonstrate additional benefit with NO measurements. Disappointingly, to date, there are no convincing data to show clinical utility of exhaled NO in guiding management of children with asthma.[185] It is apparent that exhaled NO is a steroid sensitive marker with potential clinical utility to demonstrate adherence to maintenance therapy. The exhaled NO suppression test demonstrated the distinction between adherent and nonadherent patients following a period of directly observed therapy.[186] Nonadherent patients had a greater reduction in exhaled NO after a period of directly observed therapy compared to patients who were adherent. Exhaled NO is paradoxically reduced in CF, which may reflect the high degree of oxidative stress and generation of superoxide anions that combine avidly with NO to form peroxynitrite, and high concentrations of which are detectable in CF airways. It is also reduced in PCD, which is generally characterized by a less severe airway disease than CF; and the mechanism of this reduction, and how it fits with the relative severity of airway disease, is still being studied.

## Other Exhaled Gases

There are other exhaled volatile markers of inflammation, but these are less well characterized than NO. Exhaled carbon monoxide (CO) reflects the activation of heme oxygenase-1, an enzyme induced by stress. Concentrations of CO are increased in asthmatic children and children with CF; however, there is a large degree of overlap with values in normal children, and environmental factors interfere with the measurements, so it is less useful than exhaled NO. Ethane is formed by lipid peroxidation in response to oxidative stress, and levels are increased in asthma and CF, but this technique requires complex measurements by gas-chromatography/mass spectrometry (GC/MS), so it is not practical in clinical studies.[187,188] Breathomics incorporates the multidimensional molecular analysis of exhaled breath by combining analysis of exhaled breath with GC/MS with electronic noses (e-noses) and metabolomics of exhaled breath condensate (EBC). The latter is a noninvasive technique that provides information on the composition of airway lining fluid, generally by high-resolution nuclear magnetic resonance (NMR) spectroscopy or MS methods.[189] Exhaled breath contains multiple hydrocarbons, and there is emerging evidence that these show different patterns in different diseases, reflecting the different components of inflammation; so each disease may have a unique "breathogram."[190,191] There are no studies to indicate that these measurements are useful in the clinical management of children.[175] An electronic nose (e-nose) is an artificial sensor system that consists of an array of chemical sensors for detection of volatile organic compound profiles (breathprints) and an algorithm for pattern recognition. They are handheld, portable devices that provide immediate results.[192] E-noses may discriminate between patients with different respiratory disease, including asthma, chronic obstructive pulmonary disease (COPD), and lung cancer, and healthy control subjects; e-nose breathprints are also associated with airway inflammation activity.[192] The pattern of volatile organic compounds has been shown to identify the presence of airway bacterial colonization in clinically stable patients with COPD.[193]

## Exhaled Breath Condensate

Exhaled breath condensate (EBC) is formed through condensation of cooled exhaled breath and has been analyzed for a variety of mediators, including hydrogen peroxide, lipid mediators, purines, and cytokines.[194,195] Measurement of pH has shown differences between diseases,[196] but it is difficult to interpret these data because the hydrogen ion concentration differences seem unphysiological and do not correlate with direct measurements of airway surface pH at bronchoscopy.[197] Differences in the patterns of mediators are found between asthma and CF, reflecting the different inflammatory mediators in the respiratory tract. Exhaled 8-isoprostane is a useful measurement of oxidative stress, with increased concentrations in severe asthma and CF. The concentrations of mediators in EBC are low; therefore sensitive assays are needed and great attention must be paid to the collection procedure and the avoidance of salivary contamination. Innovative approaches in the future will include metabolomic analysis, in which multiple metabolites are monitored, giving unique patterns for each disease.[198] The term *metabolomics* refers to the quantitative analysis of sets of small compounds from biological samples with molecular masses less than 1 kDa that usually require sophisticated instrumentation. The practical success of clinical metabolomics hinges on a few key issues such as the ability to capture a readily available biofluid that can be analyzed to identify metabolite biomarkers with the required sensitivity and specificity in a cost-effective manner in a clinical setting.[199] A systematic review of adults with asthma has shown that concentrations of exhaled hydrogen ions, NO products, hydrogen peroxide, and 8-isoprostanes were generally elevated and corresponded to lower lung function tests in adults with asthma compared to healthy subjects, but longitudinal studies, using standardized analytical techniques for EBC collection, are required before the tool can be used reliably.[200] EBC has never been shown to be a useful clinical tool in pediatric chest disease. A thorough review of the utility of breath biomarkers in pediatric airway diseases has shown several volatile organic compounds in exhaled breath with the potential to distinguish affected patients from healthy controls and to monitor treatment responses.[201] However, the lack of standardization of collection methods and analytical techniques hampers the introduction of these techniques to clinical practice. The measurement of metabolomic profiles may have important advantages over single markers, but this remains at very early stages. Furthermore, there is a lack of longitudinal studies and external validation to reveal whether exhaled breath and EBC analysis have benefit in the diagnostic process and follow-up of children with respiratory diseases. In conclusion, the use of volatile organic compounds and biomarkers in EBC for evaluation of inflammatory airway diseases in children remains a research tool, but it is not validated for clinical use.[201]

## Is AHR an Inflammatory Surrogate?

The first adult study to suggest that something more than standard monitoring improved asthma outcomes used AHR measurement over a 2-year period and demonstrated that a strategy aimed at normalizing AHR led to a greater use of inhaled corticosteroid and improved asthma outcomes.[202] There is one such pediatric study, which showed minor evidence of benefit using an AHR strategy.[203] This is not likely to be a clinically useful strategy; the measurements are time-consuming, and there are only loose relationships between inflammation and AHR[204] and between changes in AHR and changes in inflammation.[205,206]

## Other Potential Indirect Inflammatory Markers

There have been studies of blood and urine levels of various eosinophil proteins, but there is no evidence that their routine measurement in clinical practice is useful. Elevations in these proteins may be due to an extrapulmonary atopic disease, such as eczema or rhinoconjunctivitis, leading to a lack of specificity.

## Is There a Role for Assessing Inflammation in Pediatric Respiratory Disease?

Despite a profusion of research papers, no single set of guidelines has made an evidence-based recommendation that inflammometry should be a routine clinical tool.[207] This may be due in part to a false perception that measurement of an inflammatory marker will mean perfect sensitivity and specificity, with no need to make any other measurement. It is interesting to compare the expectations of inflammatory markers compared to what spirometry has delivered. No one would suggest abandoning spirometry, a routine measurement in every good asthma clinic, but spirometry is rarely diagnostic of asthma, correlates poorly with disease severity, and is a poor endpoint in clinical trials. It is likely that, as with spirometry, measurement of airway inflammation will find a role as part of the assessment process.

There is no gold-standard diagnostic test for asthma. Many different physiologic measurements of airway caliber and responsiveness can be made; in general, they have poor sensitivity but reasonable specificity for the diagnosis. Most clinicians would take the view that the more such tests are performed and the more that are negative, the more critically an alternative diagnosis should be sought. It may be that measurements of airway inflammation should be used in the same way.

In terms of monitoring asthma, it is clear that if the basics are right, most asthmatic children respond well to low-dose medications, and there is not likely to be a role for assessments of inflammation. Whether such assessments have a role in severe asthma is discussed in Chapter 46. However, just as reports of severe symptoms of asthma in conjunction with no evidence of AHR should lead to a suspicion of over reporting, perhaps the same will be true for those with reports of severe symptoms and no evidence of inflammation.

In summary, currently, there is no evidence that measurement of airway inflammation should be used routinely. There are hints of a possible role in the future, perhaps if it can be shown in children, as well as adults, that there are patients with discordance between inflammation and symptoms. Disappointingly, much more work is needed to determine which inflammatory markers should be measured, and in which children.

## Therapeutic Implications

Inflammation is a key feature of asthma and CF, so antiinflammatory treatments should play an important role in therapy. Inhaled corticosteroids have become the first-line therapy for asthma in children, as low doses are usually sufficient to control asthma. However, in severe asthma, there is cellular and molecular resistance to the antiinflammatory effects of corticosteroids.[208] The inflammation in CF is also corticosteroid-resistant, and adverse effects have resulted from antiinflammatory therapy. Better understanding of the inflammatory mechanisms involved in severe asthma, and CF should lead to more effective therapies in the future.[209]

## Conclusion

Airway inflammation is a critical component of many chronic airway diseases in children. The inflammatory response involves many different inflammatory cells that are recruited to and activated in the airways. Each of these cells releases multiple mediators, which then exert effects on the airway wall. In asthma, the major effects are bronchoconstriction, whereas in CF, the predominant response is mucus hypersecretion and airway wall destruction, ultimately leading to respiratory failure. Among the multiple mediators of inflammation, cytokines play an important role in orchestrating the inflammatory response and amplifying and perpetuating inflammation, whereas chemokines play a key role in selective recruitment of inflammatory cells to the airway. The molecular basis of inflammation is now understood better, with increased expression of multiple inflammatory genes, which are regulated by transcription factors. Endogenous antiinflammatory mechanisms counteract these effects, and there is some evidence that the mechanisms are defective in asthma, allowing inflammation to become more severe or to persist longer. This complex inflammatory process should be monitored in the management of airway disease, and there are several noninvasive approaches, including exhaled NO, and minimally invasive approaches such as sputum induction and assessment of the mucosal lining fluid, that look promising. Corticosteroids are highly effective in suppressing inflammation in asthma, but they are poorly effective in severe asthma and are ineffective in CF as the result of several corticosteroid-resistance mechanisms. Novel therapeutics that target the molecular mechanisms mediating inflammation in specific airway diseases should be pursued to allow effective reduction of proinflammatory pathways and promotion of regulatory or homeostatic pathways.

### 8

# Lung Defenses

## Intrinsic, Innate, and Adaptive

*Keely Garrett Smith MD, Ankur A. Kamdar MD, James M. Stark MD, PhD*

## Intrinsic Lung Defenses

Intrinsic defenses arise from the very structure of the conducting airways and the lung surfaces. The anatomy of the airways and airflow properties of the lung remove particles due to impaction or settling. Once they interact with the airway surface, these particles can elicit reflexes to remove them from the airway (sneezing or cough).

### Aerodynamic Filtering

The anatomy of the upper and lower airways contributes to the defense of the lungs against infection. The nose provides the initial filtration and humidification of inspired air because of its structure and surface area. Very large particles are filtered by the nasal hairs, and particles larger than 10 μm impact on the surfaces of the turbinates and septum.[1] Impaction is facilitated by the inertia of large particles that have a high linear velocity and do not easily change direction to follow air flow. The tonsils and adenoids are strategically located to deal with larger soluble particles by specific local defenses. If the tonsils and adenoids are markedly enlarged, nasal resistance increases. This potentially results in mouth breathing, bypassing the nasal anatomic defenses. Edema of the turbinates from viral infections or allergies may produce similar effects. Hydrophilic particles are enlarged by humidification of the inspired air, and this facilitates their impaction in the upper airways.

Particles between 2 and 10 μm are removed from the air flow by impaction on the walls of the branching airways beyond the nose, and by sedimentation. Sedimentation occurs because the increasing cross-sectional area of the conducting airways leads to a decrease in the linear air flow velocity such that gravitational forces may act on the particles. Smaller particles (as small as 0.2 μm) may not sediment at all and are exhaled. Particles in the size range of 0.2 to 2 μm generally penetrate the airways and can be deposited in the alveoli.[2] Aerosol devices and metered-dose inhalers use particle size to direct deposition of the medication to different levels of the airway. Deposition of particles can trigger local inflammatory responses in the lung and airway reflexes.

## Humidification

Warming and humidification begins at the nose and continues distally. Ultimately, inspired air is warmed to body temperature (37°C) and 100% relative humidity. Adequate hydration of airway mucus is essential to its proper functioning. The upper airway receives some humidity from convection of warm, humidified alveolar gas. During exhalation, the temperature drops and condensation forms on the upper airways, keeping their surfaces wet. At the isothermal saturation boundary (the point where air becomes body temperature) air is at 100% relative humidity that remains constant as it continues to move distally. This point typically occurs below the carina and will shift, depending on ambient temperature, humidity, and volume and rate of air exchange. It will also shift distally when the upper airway is bypassed, such as by tracheostomy. It never drops to the level of the respiratory bronchioles, so that at functional residual capacity (FRC), inspired gas is at body temperature and 100% humidity in the normal airway.[3]

## Airway Reflexes

Sneezing, bronchoconstriction, and coughing are airway reflexes that act as nonspecific host defenses. Sneezing is a forceful expulsion of air that is triggered by receptors in the nose and nasopharynx and is effective in clearing the upper pharynx and nose. The mechanisms are similar to coughing (http://thekidshouldseethis.com/post/85595081892). Bronchoconstriction may prevent entry of particles into the distal airways by decreasing airway caliber and redirecting air flow away from the irritated airways. However, it also leads to increased pulmonary resistance, decreasing air velocity in the peripheral airways, and thus, increasing the likelihood of sedimentation. Coughing is a forceful expulsion of air from the lungs that is under both voluntary and involuntary control (https://curiosity.com/paths/cough-grosser-than-sneeze-curiosity-worlds-dirtiest-man-discovery/#cough-grosser-than-sneeze-curiosity-worlds-dirtiest-man-discovery). There are at least nine sensory receptors in the bronchopulmonary system located within the epithelium of the pharynx, larynx, trachea, and the bifurcations of the major bronchi. At least five of these are involved in the cough reflex, including the unmyelinated C fibers and the myelinated irritant receptors containing substance P and calcitonin-gene–related peptide (CGRP).[4] These receptors can be stimulated by inflammatory mediators, chemical irritants, osmotic stimuli, and mechanical stimulation. Stimulation of respiratory afferents results in cognitive awareness of breathing and the urge to cough. The transient receptor potential (TRP) class of ion channels expressed on sensory neurons have recently been implicated in perception of noxious stimuli that lead to cough.[5] The reflex of cough is initiated by stimulation of afferent fibers leading to the vagus nerve that connect to the cough center in the medulla oblongata and conscious awareness in the suprapontine brain. Efferent fibers transmit stimuli along the vagus nerve and spinal cord to the larynx, diaphragm, chest wall, and abdominal muscles to produce cough. After the cough, a feedback loop occurs to determine if the cough relieved the stimulation to cough. The cognitive urge to cough is an integration of respiratory afferents, respiratory motor system, affective state, attention, learning, and experience.[6]

# The Mechanics of Cough and Abnormalities in the Cough Reflex

Six phases of cough create high air flow velocities that produce the shear forces required to clear mucus from the airway walls and to promote its expulsion through the larynx.[7]

1. *Irritation phase*—cough triggered by stimulation of the irritant receptors in the tracheobronchial tree
2. *Inspiratory phase*—initiated by a deep breath, which is usually 1.5 to 2 times the tidal volume. Air enters the airway distal to secretions. The length-tension relationships of the respiratory muscles are increased and optimized for contraction, elastic recoil potential increases, and the bronchi dilate.
3. *Glottic closure*—necessary to build pressure for subsequent phases of cough
4. *Compression phase*—begins with closure of the larynx and is followed by contraction of the intercostal muscles and abdominal musculature, which rapidly leads to increased intrathoracic pressure (up to 300 cm $H_2O$ or more in normal adults). This phase is fast, lasting approximately 200 msec.
5. *Expulsive phase*—initiated when the glottis opens and high air flows are achieved. Following the glottic opening, the airways may collapse by as much as 80% in tracheal cross-sectional area, which further increases the velocity of exhaled gas (approaching 25,000 cm/sec the speed of sound) shearing mucus from the airway walls. The cough may be interrupted by a series of glottic closures, each with its own compressive and expulsive phases. These "spikes" in flow (flow transients) can improve cough effectiveness by increasing the shear forces. In patients with significant tracheomalacia, the equal pressure point may be quite proximal and limit cough effectiveness. Efforts to move this point distally (e.g., positive expiratory pressure device at the mouth) improve cough effectiveness.
6. *Relaxation phase*—characterized by a decrease in intrathoracic pressure associated with relaxation of the intercostal and

abdominal muscles.

Abnormalities of the cough mechanism can result in an ineffective cough. Cough receptors are not present in the alveoli or lung parenchyma, and therefore coughing can be absent in children with extensive alveolar disease or consolidation. A decrease in the sensitivity of the cough center occurs in obtunded patients and individuals under the influence of opiates. The efferent nerves can be affected by poliomyelitis or infantile botulism. The muscular force needed to generate the cough can be decreased by neuromuscular diseases such as spinal muscular atrophy or muscular dystrophy. Laryngeal disorders such as vocal cord paralysis or the presence of a tracheostomy tube prevent laryngeal closure so that the cough can lose its explosive quality. The use of cough-assist devices may be useful in enhancing airway clearance.[8,9]

# Innate Lung Defenses

Innate immunity provides immediate defense against a wide variety of pathogens or noxious substances without previous exposure to them. Innate immunity can remove infectious agents from the airway by binding and trapping them for removal (mucus and mucociliary clearance). Several PRRs recognize conserved patterns of molecular structures on pathogens (pathogen associated molecular patterns, PAMPs). Engagement of PRRs can activate cascades of intracellular signals producing inflammatory cytokines and chemokines that recruit and activate effector cells. Innate PRRs and receptor proteins facilitate cellular adhesion, and activation of soluble bactericidal factors such as complement. Secreted proteins contribute to innate lung defenses (e.g., the collectins and antibiotic proteins). There are resident innate immune cells that function as “first responders” to infection (dendritic cells [DC], macrophages, and mast cells). These “first responders” not only fight infection, but also produce mediators that recruit “early responders” from the circulation. These defenses protect the lung before adaptive immune processes can develop.

## Mucus and Airway Surface Liquid

Mucus and mucociliary clearance are essential components of innate mechanical defenses in the lungs. Airway mucus is a complex network of mucins, electrolytes, enzymes, and protein defenses that immobilize, destroy, and remove noxious particles, foreign bodies, and invading microorganisms from the airway. It is the first line of innate defense in the lung.[10,11]

The airways between the larynx and the respiratory bronchioles are lined by ciliated columnar epithelium and covered by an airway surface liquid (ASL) layer that is 5 to 100 μm thick. Mucus provides several important airway defense functions: It (1) provides a covering sheet that entraps particulate matter and microorganisms; (2) is a movable medium that can be propelled by cilia (the tips of cilia drive the mucus gel layer toward the oropharynx); (3) provides a waterproofing layer that acts to reduce fluid loss through the airways; (4) detoxifies noxious inhaled irritants; and (5) transports essential secreted substances such as enzymes, defensins, collectins, antiproteases, and immunoglobulins (discussed later).

ASL consists of two distinct layers: the low-viscosity periciliary gel layer (PCL) adjacent to the epithelial surface, and the mucus layer that floats on the PCL. The viscoelastic mucus layer is composed of secreted mucus glycoproteins (termed mucins) in addition to several secreted products. These mucins have high molecular weight, are long (0.5 to 20 μm), and are highly glycosylated and branched. MUC5AC and MUC5B are the major mucins in the mucus layer. Studies in gene knockout mice demonstrate that MUC5AC and MUC5B play distinct and important roles in airway homeostasis. The PCL is made up of the tethered surface mucins (MUC1 [MUCIN 1, cell surface associated], MUC4 [MUCIN 4, cell surface associated], MUC16 [MUCIN 16, cell surface associated], MUC20 [MUCIN 20, cell surface associated]) and is approximately the height of the cilia (7 μm). These tethered mucins provide a brushlike network that prevents penetration of inhaled particles and organisms to the epithelial surface. The PCL layer is crucial because it provides a low-viscosity fluid in which the cilia can beat rapidly (8 to 20 Hz), moving the more viscous mucus layer over it and shielding the epithelial surface from the substances trapped in the overlying mucus layer. The diversity of the carbohydrate side chains of the mucin macromolecules provides a library of carbohydrate sequences that can bind to an enormous repertoire of particles that land on the mucus layer.[10–12]

The properties of this mucin gel are the product of the mucin and water contents, concentrations of monovalent and divalent ions, and the pH of the ASL. The water content of ASL is controlled by regulating levels of ion transport in the PCL layer via chloride channels (cystic fibrosis transmembrane conductance regulator [CFTR] and a calcium-activated [alternative] chloride channel), and the epithelial sodium channel (ENaC).[11,13] These channels control $Na^+$ reabsorption and $Cl^-$ secretion by the respiratory epithelial cell via energy dependent mechanisms, with passive movement of water across the epithelial membrane in response to ion transport. There is active sensing of the mucus depth and viscosity by the underlying epithelium through cilia interaction with the overlying mucus. Increase in the "strain" on ciliary movement is transmitted through the cilial shaft, resulting in release of adenosine triphosphate (ATP) from the epithelial cell. The extracellular ATP activates purinoreceptors that inhibit sodium reabsorption through ENAC and accelerate $Cl^-$ secretion through CFTR and the calcium activated channel, resulting in a net fluid secretion onto the airway surface.[11] The mucin concentration in the PCL is greater than that of the mucus layer, resulting in a higher osmotic pressure in the PCL (~500 Pa) compared to that of the mucus layer (~100 Pa). This difference in osmotic pressures makes the overlying mucus layer a "reservoir" for fluid in the airway and helps maintain the depth of the PCL layer.[11] Inflammation can result in the deposition of large macromolecules such as DNA and polymerized actin from white cells, proteoglycans, biofilms, and other combinations of bacteria and inflammatory cells that can significantly increase the viscosity of the mucus. This increased viscosity of the overlying mucus layer increases its osmotic pressure, resulting in the equilibration of the osmotic pressures of the mucus and PCL layers and potential depletion of the PCL, eventually resulting in in the "collapse" of the ASL and loss of normal ciliary function.

Ciliary beat frequency and the effectiveness of the ciliary beat are the primary determinants of the mucus clearance rate. Ciliary motion is broken down into two steps: a unidirectional power stroke that sweeps forward and a recovery phase in which the cilia bend backward and extend to their starting position. Ciliary movement occurs within the same plane so that the movement is forward and backward without any lateral movement.[14] Cilia also impart a vertical motion within the mucus layer, mixing particles, bacteria, and other pathogens into the mucus and facilitating their clearance. The lubricating effect of the mucous layer on the surface of the PCL allows the cilia to propel the overlying mucus layer with ease.

## Disorders of the Mucociliary System

**Primary ciliary dyskinesia (PCD)** is a genetic disease associated with defective ciliary structure and function, with resultant chronic oto-sino-pulmonary disease, male infertility, and (in about half of patients) *situs inversus.* Cilia are complex structures composed of a highly organized array of microtubules and accessory elements, including inner and outer dynein arms, radial spokes, and nexin links (see Chapter 71). Disruption of this structural organization has been associated with ciliary immotility or dysmotility. Measurements of mucociliary clearance in patients with PCD have revealed no basal, cilia-dependent mucus clearance, although cough-dependent clearance is nearly normal. These patients maintain a nearly normal mucus clearance rate by increasing the dependence on cough. As a result, these patients exhibit milder airway disease than seen in cystic fibrosis (CF) and typically live into middle age and beyond. However, bronchiectasis and obstructive airway disease may occur in preschool children.

**CF** results from mutations in the respiratory epithelial inducible chloride channel (CFTR; see Chapters 49 to 53). In people with CF, mucus transport appears to be significantly altered by depletion of ASL and pH and electrolyte alterations that result from mutations in CFTR. Resulting defects in $Na^+$ and $Cl^-$ transport result in volume depletion on the airway surfaces which, in turn, depletes the PCL, disrupts normal ciliary activity, and inhibits mucociliary clearance.[13]

## Adhesion Proteins

Adhesion and migration of circulating inflammatory cells (or their progenitors) are integral to cell recruitment and activation response to injury (Fig. 8.1).[15,16] Three major families of adhesion molecules participate in these processes in the lung: the immunoglobulin superfamily, the integrins, and the selectins.

**FIG. 8.1** Schematic process of neutrophil adhesion and transendothelial migration. In response to inflammatory stimuli, adhesion molecules such as selectins are upregulated on endothelial cells and neutrophils, and neutrophils roll along the vascular endothelial wall through selectin-mediated weak interactions (I). This is followed by firm adhesion of neutrophils to endothelium through binding of integrins (LFA-1, CD11a/CD18; Mac-1, CD11b/CD18; p150,95) on the neutrophil surface to ICAM-1 or VCAM-1 on the endothelial cell surface through VLA-4 (II). Subsequently, neutrophils transmigrate through the microvascular endothelium via a process involving complex interactions with endothelial cell-cell junction molecules, including VE-cadherin, JAM-1s, and PECAM-1 (III). RR, Wu MH. Neutrophil transmigration, focal adhesion kinase and endothelial barrier function. *Microvasc Res*. 2012;83[1]:82-88.)

The immunoglobulin superfamily is a group of polypeptide genes characterized by the presence of one or more regions homologous to the basic structural unit of the immunoglobulin gene. Immunoglobulins and the T cell receptors (TCRs) are the only members of this family that undergo somatic diversification for antigen recognition (adaptive immunity). Several members of this family are required for cell-cell adhesion and migration of leukocytes from the vascular space into the airway.[17,18] Moreover, they are required for adaptive immune responses (antigen presentation to T cells by DC and macrophages).

The integrins are a diverse family of molecules that are involved in cell-substrate or cell-cell interactions. The integrins are composed of two noncovalently associated polypeptide chains ($\alpha$ and β). In humans, there are 18 $\alpha$ and 8 β subunits that form 24 different heterodimers.[19] Subgroups of this family are defined by common, shared β chains. β1 integrins function primarily by interacting with matrix components (collagen, laminin, fibronectin). Very Late Antigen 4 (VLA4, $\alpha$4β1) is expressed by lymphocytes and monocytes. The β2 integrins (heterodimers of CD11 and CD18) are expressed almost exclusively on leukocytes and mediate cell-cell adhesion.[16] Upon binding their extracellular ligands, integrins transmit signals that regulate various cellular functions (see Fig. 8.1).[16] Integrins are critical for maintaining endothelial integrity, repair of damaged cells, and regulation of cell differentiation and proliferation.[19] The importance of the β2 integrins in leukocyte recruitment is demonstrated in patients with leukocyte adhesion deficiency type 1 (LAD1), as characterized by recurrent bacterial skin and soft-tissue infections, diminished pus formation, and impaired wound healing.[20]

Selectins are glycoproteins rich in O-linked and N-linked carbohydrates that mediate adhesion between leukocytes and vascular endothelium (see Fig. 8.1).[21] The N-terminal ends of these molecules function as calcium-dependent carbohydrate lectin molecules.[16] Three selectins have been identified: E-selectin (ELAM-1 [endothelial leukocyte adhesion molecule-1]), P-selectin, and L-selectin (LECAM-1 [leukocyte-endothelial cell adhesion molecule]).

E-selectin is expressed on endothelial cells following stimulation by cytokines (such as IL-1 or tumor necrosis factor-$\alpha$) and supports neutrophil adhesion. L-selectin is expressed on all leukocytes and is shed following adhesion to endothelial cells. P-selectin mediates cellular adhesion of neutrophils and monocytes to activated platelets and endothelial cells.

## Pattern-Recognition Receptors in Lung Innate Immunity

The innate immune system utilizes a wide repertoire of conserved membrane-associated or soluble PRRs able to identify pathogens or cellular injury and initiate host defenses. These include the Toll-like receptors (TLR), nucleotide-binding leucine-rich repeat (LRR) containing receptors (NLR), retinoic acid-inducible gene 1 (RIG-1)-like receptors (RLR), C-type lectins (CTLs), and absent-in-melanoma (AIM)-like receptors (ALR). This pattern recognition receptor (PRR) recognizes patterns of sugars, ribonucleic acid (RNA), and deoxyribonucleic acid (DNA) as PAMPs that function as danger-associated molecular patterns (DAMPs). Through interactions with various cellular signaling cascades, they initiate and modulate inflammation, detect metabolic changes in the cell or cell death, and develop adaptive immune responses.

### Toll-Like Receptors

The TLRs are a highly conserved family of membrane-associated PRR that have been identified in plants, insects (drosophila), and animals (mouse, human). They have two functional regions. The extracellular domain recognizes an array of microbial components: sugars, proteins, lipids, DNA motifs, and double-stranded RNA. The intracellular region contains a Toll/IL-1 receptor (TIR) domain that provides an intracellular scaffold interacting with a number of “adapter” proteins to initiate and integrate signaling cascades that result in cellular activation and the production of several cytokines and chemokines (Fig. 8.2).[22] Ten TLRs have been described in humans, and they are expressed by cell types involved in both innate immune defenses (such as macrophages, neutrophils, and airway epithelial cells) and adaptive immunity (macrophages, DC and lymphocytes). Ligands have been identified for all but TLR10 (see Fig. 8.2). The TLRs can be located in the plasma membrane (TLR1, TLR2, TLR4, TLR 5, TLR6, and TLR10) or intracellularly (TLR3, TLR7, TLR8, TLR9; see Fig. 8.2). The TLR proteins can associate as homodimers or as heterodimers of different TLR proteins thereby extending the target repertoire. The TLRs can also utilize a variety of coreceptor molecules. For example, TLR2 and TLR4 interact with MD-2 (soluble extracellular protein) and CD14 in binding to LPS. Several other PRR can cooperate with TLR in response to pathogens.[23,24]

**FIG. 8.2** Toll-like receptor (TLR) pathways: receptors, ligands, and signaling. All TLR contain the extracellular tandem repeats of leucine-rich regions (LRR) that are responsible for the binding to different ligands. The cytoplasmic Toll/interleukin (IL)-1 receptor domain (TIR) interacts with adaptors including MyD88, MAL, TRIF, and TRAM. Ligand binding triggers the dimerization of surface TLR, followed by the assembly of “Myddosome” complexes that activate MAPK or NF-κB signaling, which, in turn, induce transcriptionally the

production of proinflammatory cytokines. Intracellular TLR or internalized TLR4 dimers initiate the assembly of "Triffosome" complexes for subsequent activation of interferon (IFN)-regulatory factors (IRF). TLR are also involved in the priming and activation of inflammasomes that promote the proteolytic cleavage and activation of inflammatory cytokines. *AP-1,* Activator protein 1; *CREB,* cAMP response element-binding protein; *ERK,* extracellular signal-regulated kinase; *IFN,* interferon; *IKK,* nuclear factor kappa-B kinase subunit; *IL,* interleukin; *IRAK4,* IL-1 receptor-associated kinase 4; *IRF,* IFN-regulatory factor; *JNK,* c-Jun N-terminal kinase; *LPS,* lipopolysaccharide; *LTA,* lipoteichoic acid; *MyD88,* myeloid differentiation primary response gene; *MAL,* MyD88-adaptor-like protein; *MAPK,* mitogen-activated protein kinases; *NF,* nuclear factor; *NF-κB,* transcription factor nuclear factor kappa-light chain-enhancer of activated B cells; *NLRP3,* NOD-, LRR-, and pyrin domain-containing 3; *PDN,* peptidoglycan; *ss/dsRNA,* single/double-stranded RNA; *TBK1,* TRAF family member-associated NF-κB activator-binding kinase 1; *TRAF,* tumor necrosis factor receptor-associated factor; *TRAM,* TRIF-related adaptor molecule; *TRIF,* TIR domain-containing adaptor protein inducing interferon-β. The TIR domains of the TLR interact with intracellular adaptor proteins (MYD88 or TIR-domain-containing adapter-inducing interferon-β [TRIF]+TRAM), resulting in activation of transcription factors that lead to the expression of cytokines or interferons (see Fig. 8.2).[25] In addition, activation of TLR has been implicated in the upregulation of microbial killing mechanisms such as production of nitric oxide (NO). TLR signaling in DC drive T cell differentiation into T-helper type 1 (Th1) or T-helper type 2 (Th2) phenotypes. Thus, TLR activation interfaces both innate and adaptive immune responses.[23,24]

## C-Type Lectin Receptors

CTL receptors are membrane associated PRR that can bind either carbohydrate and noncarbohydrate (lipid or protein) ligands through a conserved CTL-like domain. They are expressed primarily on myeloid cells where they function in antifungal immunity.[26]

## Nodlike Receptors

The nodlike receptors (NLR) are a family of cytosolic PRR that participates in cellular inflammatory responses, apoptosis (programmed cell death), formation of phagosomes, and transcriptional activation of major histocompatibility complex proteins (MHC). These proteins are expressed in many cell types, including immune cells and epithelial cells. There are 22 members of the NLR family in humans.[27,28] Their general structure includes a central nucleotide-binding oligomerization (NOD) domain and a C-terminal LRR domain. The N-terminal effector region varies between the different proteins, resulting in activation of diverse downstream signaling pathways. The NLR receptors participate in signal transduction, autophagy, transcriptional activation, and inflammasome assembly (see Fig. 8.2). NOD1 and NOD2 activate Rip2 kinase, leading to activation of NFκB. The NOD-like receptor pyrin domain (NLRP) family can lead to the assembly of inflammasomes, which consist of one or two NLRs, an adapter molecule ASC (inflammasome adaptor protein apoptosis-associated speck-like protein containing CARD), and caspase 1, that participate in caspase-1-mediated cell death and post translational production of mature IL-1β and related cytokines (including IL-18; see Fig. 8.2).[25] NOD2 interacts with bacteria at the cell entry site and initiates autophagosome formation. CIITA (class II, MHC, transactivator) and NLRC5 (NLR family, CARD Domain Containing 5) are transactivators of the MHC in the nucleus.[27]

## RIG-Like Receptors

RIG-like receptors (RLRs) are cytoplasmic RNA helicases that recognize nonself RNA motifs. RIG-1 binds to 5′ tri and diphosphates present on short double stranded (ds) RNA, whereas MDA5 binds to long dsRNA molecules. Both helicases signal through the downstream adaptor MAVS (mitochondrial antiviral signaling) activating the IRF3/7-dependent production of type 1 interferons and NFκB-mediated production of proinflammatory cytokines.[29]

### Absent-in-Melanoma-Like Receptors

ALRs are a small group of PRR that can interact with ASC to form inflammasomes activating caspase 1 resulting in production of IL-1 and IL-18 (see Fig. 8.2). These PRR interact with both bacterial and viral derived dsDNA and are located in both the cytoplasm and nucleus.[30]

## Soluble Extracellular Pattern-Recognition Proteins

The soluble extracellular pattern-recognition proteins can be transfer from the bloodstream (complement, mannose binding lectin [MBL]) or secreted directly into the airway epithelium (surfactant proteins A and D) and provide innate defenses in the lung by carbohydrate recognition domains (CRDs). Several members of the collectins and ficolins activate complement.

### Complement

Complement proteins play an important role in lung defenses. Complement components arrive in the lung both by extravasation due to vascular injury and leak and by local production by the respiratory epithelium and macrophages.[31] Complement activation occurs by three pathways (classical, lectin or alternative) and contributes to host defense through several mechanisms:

- opsonization by deposition of complement components on the pathogen surface
- activation of phagocytic cells by the local release of chemotactic agents (e.g., C5a)
- lysis of pathogens through the activation of the late components C5, C6, C7, C8, and C9
- generation of anaphylatoxins (C3a and C5a) that

cause the release of vasoactive mediators from mast cells

- generation of C3b and C4 on cell surfaces that bind to receptors on phagocytic cells.[31]

Complement deficiency is associated with recurrent infections, glomerulonephritis, or collagen vascular diseases such as systemic lupus erythematosus.[32]

## Collectins

The collectins are a family of collagenous, calcium-dependent (C-type) lectins, including MBL (mannose-binding lectin) and surfactant-associated proteins A and D (SP-A and SP-D, respectively). They have a key role as a first line of innate defense against invading microorganisms in the airway. Both SP-A and SP-D are secreted into the air spaces by alveolar type II cells and nonciliated bronchiolar cells. Selective binding of collectins to specific complex carbohydrates is mediated by the CRD and requires calcium. Human SP-A is assembled as heterotrimers or homotrimers of two genetically different chain types and forms hexamers of these trimeric subunits (6 × 3 = 18 chains). SP-D is assembled as homotrimers that form tetramers (4 × 3 = 12 chains).[33] This arrangement of subunits increases the binding affinity and specificity: multiple CRD domains can simultaneously bind to different ligands on a single polysaccharide chain, increasing the binding avidity of the complex. SP-A and SP-D interact with a variety of gram-negative and gram-positive organisms, fungi, and viruses including respiratory syncytial virus (RSV), Influenza A virus, and cytomegalovirus (CMV). Lung collectins can lead to opsonization through activation of complement and deposition of C3 (MBL) or can directly opsonize microorganisms (SP-A and SP-D), leading to phagocytosis and pathogen killing. SP-A binds to LPS and interacts with CD14 and TLR4, suggesting a role for SP-A in LPS-mediated cell responses. MBL is produced in the liver but is found in the lung at sites of inflammation. MBL is a serum protein, although small amounts of this protein have been found in lung secretions.

The ficolins are lectin recognition molecules that are structurally and functionally homologous to MBL. Three ficolins have been described. Ficolin-1 (M-ficolin) is expressed in the lung, monocytes, and spleen. Ficolin-2 (L-ficolin) is a serum protein expressed in the liver. Ficolin 3 (H-ficolin) is expressed in liver but also by bronchial and type II alveolar epithelial cells. They share the collagenous structure of MBL, but the CRD of MBL is replaced by a fibrinogen-like domain. They assemble in large multimeric structures of several hundred kilodaltons and recognize molecular patterns such as acetylated compounds and sugars. Similar to MBL, they activate complement through the lectin pathway.[34]

## Antimicrobial Peptides

Several intrinsic microbiocidal and microbiostatic proteins are found in human respiratory secretions, including lysozyme, lactoferrin, secretory leukoprotease inhibitor (SLPI), and neutrophil and epithelial defensins.

Lysozyme is the one of the most abundant antimicrobial proteins in the airways with concentrations estimated at 0.1 to 1 mg/mL, which is sufficient to kill important pulmonary pathogens such as *S. aureus* and *P. aeruginosa.* Lysozyme damages the walls of bacteria and fungi by hydrolyzing β1–4 glycosidic bonds between N-acetylmuramic acid and N-acetylglucosamine, structural components of bacterial peptidoglycan and fungal chitin. In humans, lysozyme is secreted predominantly by the serous cells of submucosal glands in the conducting airways, and, to a lesser extent, by airway epithelial cells and alveolar macrophages (AM). It is also a component of both phagocytic and secretory granules of neutrophils.[35]

Lactoferrin is present in tears, saliva, and bronchial secretions. It is present in ASL at concentrations similar to lysozyme (0.1 to 1 mg/mL). It is produced by the submucosal glands and neutrophils and has activity against both gram-positive and gram-negative bacteria and *Candida* species. The antimicrobial actions of lactoferrin results from iron chelation (iron is required by many bacteria for optimal growth) or from destabilization of bacterial membranes.[36]

SLPI and elafin were originally described as protease inhibitors. They have subsequently been shown to have a wider range of biologic activities.[37] SLPI is an 11.9-kDA protein about 10-fold less abundant than lysozyme and lactoferrin in ASL. The N-terminal domain has modest activity against both gram-positive and gram-negative organisms. The C-terminal domain is an effective inhibitor of neutrophil elastase, cathepsin G, trypsin, chymotrypsin, tryptase, and chymase. Elafin/Trappin-2 is a 9.9-kDA protein that has a narrower spectrum of protease inhibition (only inhibiting neutrophil elastase and proteinase 3). In addition, the protease inhibitors exhibit antiinflammatory effects on NFκB activity and antimicrobial activity against a number of organisms, including *Staphylococcus aureus* and *Pseudomonas aeruginosa*. SLPI may also play a role in adaptive immunity through maintenance of mucosal tolerance.[37]

Human defensins are antimicrobial peptides (3 to 5 kDa) found in BAL fluid from noninflamed lungs at a concentration of about 100 ng/mL, but at increased levels in inflamed airways. Four human alpha defensins, (human neutrophil defensins 1-4, human neutrophil peptide [HNP]-1, HNP-2, HNP-3, and HNP-4) are found in neutrophil azurophilic granules. Four beta-defensin molecules have been described (hBD-1, hBD-2, hBD-3, and hBD-4). hBD1 is expressed constitutively by epithelial cells, while hBD2 to hBD4 are inducible. In addition to their antimicrobial effects, defensins help recruit inflammatory cells and promote both innate and adaptive immune responses.[38]

Cathelicidins are peptides produced by neutrophils and respiratory epithelial cells that have functions similar to those of defensins.[38] The human cathelicidin (LL-37) displays LPS-binding activity and broad-spectrum microbiocidal activity.

## Cellular Defenses: at the Crossroads of Innate and Adaptive Immunity

Our knowledge of the cellular constituents in the lung, their activation state, and their function has been considerably augmented by the flexible fiberoptic bronchoscopy and biopsy. Using bronchoalveolar lavage (BAL), the normal cellular constituents of the airway and alveolar space have been measured in both adults and children. In normal subjects, macrophages are the major cellular component of BAL, making up 81% to 95% of the cells; the remaining cells are lymphocytes, neutrophils, and eosinophils. The BAL cell number and percent composition vary greatly in disease states.[39] Data obtained from BAL and biopsy studies provide direct evidence of the role of inflammatory cells, adhesion molecules, and cellular mediators in humans, confirming findings in cell culture and animal studies.

## The Respiratory Epithelium

The respiratory epithelium is a functional interface between the pathogen and the innate or adaptive immune responses, making it a pivotal structure in respiratory physiology and pathology.[40] The respiratory epithelium participates in lung immunity in many different ways. The epithelium provides physical barrier to infection, lining the respiratory tract from the nose to the alveoli with a wide range of cell types.[41] Ciliated epithelial cells are important in propelling mucus up the airway, thereby removing particulate material. Ciliated cells line the respiratory tract down to the level of the respiratory bronchiole. Tracheobronchial glands and goblet cells are important sources of airway mucus, which serves to nonspecifically trap particulates. The respiratory epithelium also functions in the regulation of water and ion movement into the airway mucus.[40] It secretes SP-A and SP-D, lysozyme, lactoferrin, and antimicrobial peptides (β-defensins and cathelicidins),[42] and releases reactive oxygen and nitrogen species to kill invading pathogens.[43] The respiratory epithelium can produce a number of bioactive cytokines that recruit and activate inflammatory cells in the lung (interferon [IFN]-α, IFN-γ, IL-1, TNF-α, IL-8, RANTES [Regulated on Activation, Normal T Cell Expressed and Secreted]). The respiratory epithelium influences adaptive immunity through cytokine release: fostering a Th2-like response through release of IL-25, IL-33, and TSLP (thymic stromal lymphopoietin). The epithelium promotes recruitment and activation of DC and lymphocytes (CCL20) and mast cells (stem cell factor [SCF], IL-33, TSLP release). The respiratory epithelium also acts as its own reservoir for injury repair. Finally, the epithelium promotes remodeling through release of transforming growth factor-beta (TGF-β). It is therefore a key modulator of lung defense, lung injury, and repair.[40,43]

## Resident Cell Defenses: At the Interface of Innate and Adaptive Immunity

Three major groups of inflammatory cells reside primarily within the lung parenchyma itself: DC, macrophages, and mast cells. The cells (particularly the macrophages and DC) are capable of migration; however, they reside primarily within the lung itself. Other inflammatory cells are recruited from the circulation in their mature form (neutrophils, eosinophils, and lymphocytes) and become activated in the lung. The pulmonary DC and macrophages participate in both innate and adaptive immune responses in the lung.[44]

### Dendritic Cells.

DC are the primary resident antigen-presenting cells in the lung and airway.[44] Activation of DC in response to innate stimuli is essential to initiate the adaptive response to antigens. In these processes, the phenotype and function of DC play an important role in initiating adaptive immune responses (tolerance, memory, and polarized Th1 and Th2 differentiation). Antigen presentation to T cells is actively and tightly regulated *in vivo* by soluble factors produced by mature tissue macrophages. Therefore, the phenotype of the DC, the response to innate stimuli and cytokines produced by macrophages, and the lung microenvironment play important roles in determining host adaptive responses.[45]

In humans, three different subsets of DC (2 "myeloid" and one "plasmacytoid") have been described: mDC1 (expressing BDCA1/CD1c), mDC2 (BDCA3/CD141), and pDC (BDCA2/CD123). The origin of human DC is not completely understood, but they appear to arise from common granulocyte/macrophage and multilymphoid progenitors in the bone marrow.[44] DCs have a rapid half-life in the conducting airways (about 2 days), whereas more distal lung DCs have a slower turnover rate. mDC1 cells have been associated with induction of CD8+ and CD4+ Th1 responses, whereas mDC2 cells are associated with CD4+Th2 and Th17 responses, although there is some overlap.[45,46] pDC have been ascribed an antiviral role, although in the steady state, their main role appears to be induction of tolerance.[45] mDC are associated with the airways and appear to "sample" the airway by extending dendrites through the airway epithelial layer. pDC locate mainly in the alveolar interstitium. However, they have the ability to migrate to inflammatory foci, where they can take up and process antigen, migrate through the lymphatics to the draining lymph nodes, and associate with T cell–rich areas to initiate adaptive immune responses.

### Macrophages.

The pulmonary macrophages are central regulators of airway inflammation. They exhibit mobility, phagocytosis, receptor expression for signal recognition, and production and release of a number of bioactive mediators. In the lung, they are capable of scavenging particulates, removing macromolecules, killing microorganisms, recruiting and activating other inflammatory cells, maintaining and repairing injured tissue, removing apoptotic cells, and modulating normal lung physiology.[45,47,48] Many of these functions are "turned off" in the resting state but are upregulated with macrophage activation. Therefore, regulation of macrophage activation and turnover is important in determining pulmonary health or disease.[47,48] Macrophages can cooperate with other cell types (DC, neutrophils, lymphocytes, fibroblasts) by direct cell–cell interactions and by cytokine signals to orchestrate development of cell-mediated immunity and humoral immunity.[44,47] (https://www.youtube.com/watch?v=LwLYGTS_3EI). Macrophages are more abundant in the distal respiratory tract, particularly the alveolus, than in the tracheobronchial tree. The macrophage population is usually constant in size, but this is the result of a dynamic steady state of cellular recruitment, cell division, and cell turnover. At least two types of macrophages reside in the lungs: interstitial macrophages (IM) and AM. The macrophages populating the airways above the alveolus are thought to arise from those in the alveolus. IM are in the interstitial space between alveolae where they interact with DC and interstitial lymphocytes. They promote tolerance and prevent Th2 mediated airway inflammation. The IM are thought to be derived from circulating precursor peripheral blood cells of the monocyte/macrophage lineage.[44]

AM, along with the epithelium, are the first line of defense against infection. They are mobile, traveling between the alveoli and sampling the alveolar surface.[47,49] They are phagocytic and express numerous PRR that trigger expression of cytokines, chemokines, and other reactive products (lipids, reactive oxygen, and nitrogen species) that are crucial in control of infection through the innate immune system and balance of proinflammatory and antiinflammatory pathways in the lung. The AM are classified according to their activation status as M1 or M2. M1 macrophages (also termed classically activated macrophages) respond to IFN-$\gamma$, LPS, and TNF$\alpha$ to produce proinflammatory cytokines leading to the destruction of intracellular pathogens and promoting a Th1 environment. M2 (alternatively activated macrophages) are characterized by their participation in Th2 responses. The switch to M1 or M2 phenotype is associated with the specific transcriptional response to the local microenvironment.

AM are thought to arise from yolk sac macrophages or fetal liver monocytes that enter the lung during embryonic development and colonize the alveoli in the first days after birth. AM mature under the influence of local production of CSF-2 (GM-CSF). This population of early progenitors populates the lung and self-maintains throughout the host's lifetime.[44,48] Under inflammatory conditions, some AM may arise from mononuclear cells, but these more resemble the IM in function. The turnover time for AM has been calculated to be 21 to 28 days in animal models. At the end of this time, they exit from the lungs up the mucociliary escalator, although the mechanisms for this efflux are still unknown.

AM produce a number of reactive oxygen metabolites and nitrogen metabolites and a large diverse array of enzymes (acid hydrolases, neutral hydrolases, and lysozymes) capable of killing bacteria. AM also produce cytokines and chemotactic factors that play a central role in phagocyte recruitment and activation, wound healing, fibrosis, and modulation of actions of other innate and adaptive immune responses in the lung.[47,48]

### Mast Cells.

Mast cells are the major effector cells of allergic reactions. They are distributed in tissues throughout the body in close proximity to blood vessels and do not circulate in the blood. It has been postulated that they play roles in host defense against parasites, wound healing, immunoregulation, and tumor angiogenesis. Mast cells originate in the bone marrow from granulocyte and monocyte pluripotent CD34+ and CD117+ stem cells. Homing to specific tissues is driven by active local recruitment. Growth and survival of mast cells requires stem cell factor (SCF) production by structural cells (epithelial cells, fibroblasts, endothelial cells, smooth muscle cells). SCF promotes proliferation and differentiation, chemotaxis, and suppression of apoptosis that promotes mast cell growth, recruitment, and survival.[50] Mature differentiated mast cells are capable of proliferation. Therefore, tissue-specific increases in mast cell numbers can occur by either recruitment or local proliferation.

Mast cells can express a wide variety of receptors that allow them to detect intracellular and extracellular signals and interact with other inflammatory cells and with the extracellular matrix. Ligand binding and activation of the FcεRI results in release of a number of bioactive products responsible for allergic reactions.

Mast cells participate in antigen presentation and interactions with other immune cells via costimulatory molecules or secreted products that can enhance or suppress the development of innate or adaptive immune functions.[50,51] There is strong evidence that mast cells play significant roles in atopic and nonatopic asthma, pulmonary fibrosis, pulmonary hypertension, and may contribute to acute respiratory distress syndrome (ARDS). Persistent activation of mast cells can also exacerbate Th2-dependent or autoimmune disorders.[50,51]

## Recruited Cellular Defenses

All recruited pulmonary inflammatory cells are initially derived from bone marrow precursors and arrive from the pulmonary circulation in their mature, active forms. In the process of recruitment, these cells move from a “quiescent” resting state to a state in which they are fully “activated” or “primed” for further cellular activities.

### Neutrophils.

Neutrophils are characterized by their multilobed nucleus and distinctive cytoplasmic granules that contain an arsenal of enzymes and proteins. Neutrophils constitute about half the circulating white blood cell population, and their primary function is phagocytosis and killing of invading pathogens. In order for the neutrophil to accomplish this, it must respond to signals in the area of injury, adhere and transmigrate through the vascular endothelium, migrate to the area of infection, recognize the pathogen, phagocytose, and kill it. Interruption of any of these steps will leave the host susceptible to infections. Patients with leukocyte adherence deficiency (LAD) are unable to recruit neutrophils into sites of inflammation, and, as a result, they sustain recurrent, life-threatening infections. In chronic granulomatous disease (CGD), the neutrophils lack components of the nicotinamide adenine dinucleotide phosphate hydrogen (NADPH) oxidase system, and affected neutrophils that have engulfed organisms cannot efficiently kill them. The processes of neutrophil recruitment and activation, followed by neutrophil removal (cell death, or apoptosis) after the resolution of the infectious process or injury, are closely regulated at several levels. Disruption of these regulatory processes can lead to acute or ongoing lung injury.[52]

Neutrophils are short-lived cells; their life span from stem cell differentiation to removal in the tissues is 12 to 14 days. CD34+ myeloid progenitor cells in the bone marrow produce myeloblasts, which then differentiate through several recognizable morphologic stages into mature, nondividing polymorphonuclear neutrophils. It normally takes about 14 days for the neutrophil precursor to mature and be released into the blood.[53] Once in the circulation, neutrophil half-life is quite short (~6 to 7 hours). The pulmonary capillary bed is unique in its ability to “concentrate” neutrophils. The term *margination* has been proposed to describe this increased concentration of neutrophils in noninflamed lungs. Margination is proposed to result from discordance between the diameter of neutrophils (6 to 8 μm) and the capillary segments (2 to 15 μm), increasing the pulmonary capillary transit time. This is postulated to allow neutrophils time to sense and respond to the presence of inflammatory processes.[53] In response to inflammatory stimuli, neutrophils accumulate in preparation for migration (see Fig. 8.1).

In much of the systemic circulation, neutrophil sequestration occurs in postcapillary venules in the form of rolling and is mediated by selectins. In the pulmonary capillary, inflammatory mediators alter the mechanical properties of the neutrophils, resulting in changes in deformability and "stiffening" that reduces the neutrophil deformability, lengthens the capillary transit time, or stops the movement of the neutrophil altogether at the sites of inflammation.[53] Once sequestration has occurred, the neutrophils can adhere via selectin or CD11/CD18-intercellular adhesion molecule-1 (ICAM-1) and migrate across the vascular endothelium (see Fig. 8.1). During migration into the lung, the neutrophils become activated, resulting in a change in surface receptors compared to blood neutrophils.[54] The migration and activation of neutrophils requires a number of products of the endothelium, epithelium, and AM including IL-1β, TNF-$\alpha$, IL-6, IL-8/KC, macrophage inflammatory protein (MIP)-1$\alpha$, MIP-1β, MIP-2, CCL2, G-CSF, and LTB4. Once the neutrophil has migrated into the tissue, its primary purpose is to recognize, ingest, and destroy pathogens.

Similar to the resident innate cellular defenses, neutrophils express numerous PRR and respond by production of reactive oxygen species and secretion of azurophilic granule contents (myeloperoxidase, elastase, defensins), specific granule contents (lactoferrin, cathelicidins), gelatinase granule contents (lysozyme) and the formation of neutrophil extracellular traps (NETs).[49,55] NETs are weblike structures composed of dsDNA, histones, antimicrobial peptides, and proteases ejected by neutrophils to ensnare microbes in a sticky matrix of extracellular chromatin and antimicrobial peptides, making the microbes more vulnerable to phagocytosis and clearance.[56] (https://www.youtube.com/watch?v=TIFmtnSdolM). Over-exuberant neutrophil activity can contribute to ARDS and to tissue destruction in autoimmune diseases.[55,56] There are data supporting a role for neutrophils in wound healing and homeostasis.[57]

### Eosinophils.

Eosinophils are usually the second largest group of granulocytic cells in the circulation. They can be morphologically distinguished from neutrophils by their ability to be stained by negatively charged dyes, such as eosin. They are 8 μm in diameter and typically have two nuclear lobes. Eosinophils arise from bone marrow precursor cells under the influence of a number of cytokines including IL-3, IL-4, IL-5, IL-14, and GM-CSF. IL-4 and IL-13 stimulate IgE production and promote eosinophil recruitment by increasing expression of eotaxin and endothelial cell vascular cell adhesion molecule 1 (VCAM1). IL-5 mediates eosinophil production and egress from the bone marrow, eosinophil activation, and survival.[58] The migration of eosinophils from the bone marrow takes about 3.5 days after DNA synthesis has completed. In the blood, the half-time of an eosinophil is 18 hours. Similar to neutrophils, there appears to be a marginated pool of eosinophils, which are in dynamic equilibrium with the circulating pool. Eosinophils marginate and emigrate into the tissues through postcapillary venules. Eosinophils, but not neutrophils, adhere to the ligand vascular cell adhesion molecule (VCAM)-1 on the endothelial surface and once adherent, can be attracted by a specific array of chemotactic agents into the lung. Eosinophils express the receptor CCR3 that binds eosinophil specific chemokines including eotaxin (CCL11) eotaxin-2, monocyte chemoattractant protein (MCP)-3, MCP-4, and RANTES (CCL5). Eosinophil recruitment into the lungs occurs under the influence of Th2 mediated inflammation. Once present in the lungs, eosinophils degranulate and release a number of granular components including major basic protein (MBP), eosinophil peroxidase (EPO), eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN); as well as cytokines and chemokines. Some of these cytokines promote eosinophil survival and activation. In addition, eosinophils can undergo extracellular trap cell death (ETosis) and release extracellular traps similar to those released by neutrophils. The eosinophil traps bind eosinophil granules as intact structures, unlike the traps formed by neutrophils.[59] Collectively, these eosinophil products have potent activity that implicates the eosinophil in the control of parasitic diseases. However, these proteins also have activities that are associated with the pathogenesis of a number of pulmonary disorders. Asthma is by far and away the most common eosinophil-associated lung disease in children. The pathophysiology of asthma results from contributions from a number of inflammatory cells including eosinophils, mast cells, neutrophils, and T lymphocytes.[58] In addition to asthma, eosinophils contribute to the development of a number of eosinophilic pneumonias (see Chapter 65). These can be roughly divided into primary eosinophilic pneumonias (eosinophilic granulomatosis with polyangiitis, idiopathic acute eosinophilic pneumonia, idiopathic chronic eosinophilic pneumonia) and secondary pneumonias (pneumonia in response to parasitic worms, allergic bronchopulmonary aspergillosis, drug reactions).[60]

### Innate Lymphocytes: Innate Lymphocyte Cells and Natural Killer Cells.

Over the past decade, there has been strong interest in newly described subsets of lymphocytes referred to as innate lymphocyte cells (ILCs). There are currently three groups of ILC (ILC1, 2, 3) characterized by cytokine products and transcription requirements for maturation. They display a wide variety of effector functions that contribute to defense against pathogens, to lymph node development, and to tissue remodeling. Given the ongoing research to further characterize ILCs, a full discussion is beyond the scope of this chapter, and the focus will be directed to NK cells, which comprise part of the ILC1 subset.

Natural killer (NK) cells are large granular lymphocytes that are key players in early immunity along with other cells involved in the innate immune system, including neutrophils, monocytes, and mast cells. At first, they were recognized in having cytotoxicity against tumor cells and virus-infected cells. Over the past four decades, their role has been well established in a variety of functions, including cytokine production and interaction with other immune cells to promote immune system homeostasis.[61] Although they were traditionally considered part of the innate immunity, there is a significant amount of evidence to support NK cells having a role in adaptive immunity (below). NK cells have been shown to respond to their local environment by indirectly modulating T cell effector and antigen presenting cell function, and forming immunologic memory, which are hallmarks of adaptive immunity.

Derived from the bone marrow, NK cells are characterized by CD56. Peripheral NK cells can be further divided into two subsets;

CD56$^{bright}$ and CD56$^{dim}$. CD56$^{bright}$, which are more predominant in serum, are known to be more responsive to soluble factors, while CD56$^{dim}$, which are more abundant in tissue, respond better to cell surface ligands.[62] NK cells lack a TCR/CD3 complex, and represent approximately 2% to 18% of the total lymphocyte population circulating in the blood. NK cells can initiate natural cytotoxicity via release of perforin and granzyme granules. Perforin results in pore formation on the target cell, which allows entrance of granzyme that induces apoptosis. In addition, their effector functions (enhancing cytotoxicity, inducing cytokine secretion, modulating immune homeostasis) are largely exerted by the wide and diverse number of activating and inhibitory receptors expressed on the NK cell surface. Binding of antibody to CD16 (FcγR III) on the NK cell surface induces antibody-dependent cell-mediated cytotoxicity. The natural killer cell receptors (NCR), can bind to a stressed cell, caused by infection or cellular damage. These stressed cells express ligands that the NK cell can bind to and subsequently induce cell lysis. There are several receptors that bind proinflammatory cytokines, which stimulate NK cells to respond to infection, proliferate, and promote further cytokine secretion.

Inhibitory receptors will downregulate NK cell function. Killer cell immunoglobulin like receptors (KIR) are MHC class I inhibitory receptors, and when bound to self MHC molecules, they ensure tolerance to self, preventing damage to healthy cells.

Recently, there has been a better understanding of the tissue bound NK cells, particularly in the mucosa, including uterus, and lung. These "nonconventional" NK cells are unique NK cells with varying phenotypic properties. With their proximity to the epithelia, they express unique receptors to enhance protection against the external environment as well as to provide homeostasis to prevent an exuberant inflammatory response.[62–66]

## Adaptive Lung Defenses

Most pathogens gain entry to the lung across mucosal surfaces. An important aspect of inflammatory and immune responses to the entry of respiratory pathogens is the ability to mount an appropriate, regulated immune response that can clear the infection rapidly and efficiently but not expose the surrounding tissues or the whole host to chronic inflammation. Innate immunity provides the first level of protection. Adaptive or specific immunity provides specific responses to antigens during acute infection and provides specific immune memory that protects in the event of reexposure. A number of cell types contribute to airway mucosal defense, as discussed earlier in the chapter. As part of the mucosal surface from the nasal airway to the conducting airways, the bronchial-associated lymphoid tissue (BALT) functions in the development of adaptive lung defense. The BALT is made up of intraepithelial lymphocytes, macrophages, DC, NK, and natural killer T cells (NKT) cells that recognize foreign substances, invading organisms or their exoproducts, and products of cell injury using their receptor systems. The DC or macrophages interact with lymphocytes to create the cellular immune responses, or to signal antibody production. These cells migrate to local lymph nodes, tonsils, or adenoids; process antigens; generate cytokines; and generate the adaptive immune responses. While extensive reviews of humoral (B cell mediated) and cellular (T cell mediated) immunity, antigen presentation, and cellular activation are well beyond the scope of this chapter, we will briefly discuss the roles of humoral and cellular immunity with respect to lung defense.

## Bridging the Adaptive and Innate Defenses

NKT cells are heterogeneous group of T cells that express a unique set of cellular receptors. They owe their name due to the coexpression of receptors typically found on NK and conventional T cells that likely contribute to their activation and regulation. NKT cells are characterized by Cd1 restriction. Cd1 is a MHC class I like molecule that presents lipid antigens as opposed to peptides. Activation of the NKT cells subsequently leads to rapid release of Th1 or Th2 cytokines. NKT cells function primarily to provide protective immunity against a variety of pathogens, regulate autoimmunity, and support natural immunity against tumor development.

Invariant natural killer T (iNKT) cells are a subset of NKT cells that express an invariant TCR$\alpha$ chain and a limited TCR$\beta$ chain. By recognizing foreign lipid antigens via CD1d restriction, they can contribute to defense against pathogens in a quick manner. After activation, they rapidly secrete cytokines and chemokines, including IFNγ, IL-4, and IL-17, to stimulate immune cells downstream. After their rapid innate effector functions, they can perform adaptive functions as well via activation of antigen-presenting cell (APC). The APC, in turn, upregulate expression of lipid antigens recognized by the iNKT cells, which bind to the APC. The iNKT cells are then stimulated to secrete cytokines that activate NK cells, leading to enhanced antigen presentation to MHC-restricted T cells. Thus, iNKT cells are felt to play an important role in "bridging" the adaptive and innate immune systems.[67]

γδ T lymphocytes are innate T lymphocyte populations that express the γδ TCR with limited diversity. They make up approximately 0.5% to 5% of all circulating T cells. Yet in the epithelial and mucosal tissue, they make up a significant portion of the T cell population. In humans, the Vγ9Vδ2 TCR is utilized by the majority of peripheral γδ T cells. These cells recognize small organic phosphate antigens (phosphoantigens) from microbes, which are produced by a number of intracellular pathogens, such as *M. tuberculosis.* The heterogeneity of the γδ TCR is not as diverse as αβ T cells due to the relative lower number of V (variable) γ and Vδ genes. In contrast to αβ T cells, they are not MHC restricted and can be activated by protein and nonprotein antigens. The population expands significantly in protozoan infections (e.g., malaria and toxoplasmosis) and mycobacterial infections. Downstream, activated γδ T cells can influence T cell effector function, as well as B cell activation, providing the boost to the adaptive immune response. Subsequent differential expression of IFNγ, IL-4, and IL-17 influences the development of Th1, Th2, and Th17 responses, respectively.[67–69]

## T Lymphocytes and Lung Defense

Several types of T (thymus derived) lymphocytes (T cells) contribute to lung immunity and tissue pathology. All mature T cells express a unique TCR, with the majority made up of an α and β chain (αβ), while others are composed of a γδ chain. The αβT cells make up ~95% of the T cells peripherally, although the γδ T cells can reach up to 50% in mucosa, suggesting a stronger role in lung defense. Almost all αβT cells are CD4(+) or CD8 (+). CD4(+) T cells are known as T helper (Th) cells, while CD8(+) T cells are termed cytotoxic/suppressor cells. CD4(+) T cells recognize antigens presented via the MHC class II antigen, and they provide effector function primarily by the release of cytokines. Initially, two subsets of T cells, of Th1 and Th2 were identified, characterized by their cytokine profiles, IFNγ and IL-4, respectfully, as the driver for the Th functions. IL-12 induces the Th1 pathway, and IL-4 activates the Th2 pathway. In general, the Th1 pathway helps regulate cellular immunity and Th2 pathway produces cytokines to activate mast cells and eosinophils and stimulate B cell production of immunoglobulin. Th2 cytokine network (IL-4, IL-5, IL-10, and IL-13) has been well established in the model of understanding the pathophysiology of asthma, increased production of mucus and fibrosis. Over the past decade, several other Th subsets have been identified, including the Th17 and Treg (regulatory T cell) subsets. The Th17 subset is characterized by secretion of IL-17, which plays a significant role in host defense against extracellular bacteria, autoimmunity, and asthma. Over expression of IL-17 has been associated with collagen deposition and airway inflammation. It has been identified as a potentiator at the local level that induces bronchial fibroblasts to release proinflammatory cytokines and increase airway responsiveness. It can also recruit neutrophils to the site of airway inflammation, which may contribute to the pathophysiology of steroid-resistant asthma.

Treg cells are a subset of CD4 (+) T cells which is characterized by the CD25 receptor along with coexpression of CD45. They regulate T cell effector functions via the transcriptional regulator Foxp3. Mutations in the Foxp3 subsequently lead to autoimmunity and uncontrolled lymphoproliferation. Treg cells also play a strong role in the pathogenesis of asthma. They produce IL-10, and TGF-β, which are inhibitory cytokines that help dampen the inflammatory response and downregulate airway remodeling. They also block the Th2 response, which suggests a balance of these systems in the setting of allergy and asthma.

In response to peptides presented by the MHC class I molecules, CD8(+) T cells function in target cell toxicity. CD8(+) T cell toxicity is mediated by the release of perforin and granzyme, and Fas-FasL interaction, in a similar fashion to NK cell cytotoxicity. CD8(+) cells reinforce viral defenses by rendering adjacent cells resistant to infection, presumably by the release of interferons. T cell responses are tightly regulated. Whereas responses are necessary to eliminate pathogens, uncontrolled responses can cause autoimmune inflammatory diseases.[70]

## B Lymphocytes

B (bone marrow derived) cells play a critical role in the maintenance of health largely by mediating host defense against infections and by generating a robust vaccine response. The mechanisms behind this include production of high affinity, isotype-switched antibodies, as well as regulated interaction with T cells, to stimulate T cell differentiation, activation, and formation of memory cells. The initial development of a B cell occurs in the bone marrow with subsequent maturation in the periphery in the lymphoid tissue (i.e., lymph nodes, spleen). During the maturation process, the pro-B cell undergoes V(D)J recombination to produce a vast array of B cell receptors (BCR). This subsequently leads to the expression of surface IgM BCR on an immature B cell, which leaves the bone marrow for further development in the spleen. Testing for autoreactivity occurs at multiple checkpoints, via clonal deletion, anergy, and receptor editing/revision. Activation and further differentiation of the naïve B cell (mature B cells that have not been exposed to antigen) then occurs in the peripheral lymphoid tissue. Protein antigens are considered T cell–dependent antigens, as they cannot activate B cells without T cell assistance. The antigen is bound by the BCR, endocytosed, processed, and with a small peptide, presented to the cell surface via the MHC class II receptor, which is recognized by the Th cells. They activate and release cytokines that drive maturation of B cells into plasma cells, which secrete a “class switched” antibody. More importantly, the activated T cell also exposes the CD40 ligand and binds to the B cell receptor, CD40 Receptor. With this process, the B cell undergoes somatic hypermutation and isotype class switching to develop high affinity antibodies, a process which occurs in the germinal centers of secondary lymphoid follicles. The organization of these structures provides an immune microenvironment that maximizes the generation of antibody responses by bringing all relevant cell types into close contact for cell-cell signaling. Polysaccharide antigens, considered to be T cell independent antigens, can activate B cells without assistance from T cells. Examples of T cell–independent antigens include polysaccharides and polymerized flagellin, which provide numerous repeating epitopes. T cell–independent antigens do not induce the formation of germinal centers and therefore cannot induce the generation of memory B cells or somatic hypermutation that results in the production of high-affinity antibodies. The extent of class switching from IgM to other classes of antibodies is also severely limited in the absence of Th cell–generated cytokines.[71,72]

## Humoral Immunity

Depending on the stage of development of the B lymphocyte, different immunoglobulin isotypes are produced. Prior to antigenic stimulation, the "naïve" B lymphocyte expresses IgM (and IgD) on its surface. Early in the antigenic response, IgM, IgG3, and IgG1 are produced by B lymphocytes. In the chronic response, the predominant isotypes produced are IgG2 and IgG4. In addition, IgA is important in the mucosal immune response.

### Immunoglobulin A

Secretory immunoglobulin A (IgA) is the predominant immunoglobulin isotype present in mucosal surfaces. Secretory IgA is composed of two IgA molecules (dimeric IgA), a joining protein (J chain), and a secretory component (SC). The dimeric IgA-J chain complex is produced by B lymphocytes in the submucosal tissues. The SC is produced by mucosal epithelial cells and acts as a receptor for dimeric IgA. After IgA binds to the SC, the entire complex undergoes transcytosis and is transported to the apical surface of the cell, where the secretory IgA complex is released into the mucosal environment. The SC protects the secretory IgA complex from proteases present in the mucosal environment.

Secretory IgA serves several functions, including neutralization of viruses and exotoxin, enhancement of lactoferrin and lactoperoxidase activities, and inhibition of microbial growth. Because dimeric IgA is able to bind two antigens simultaneously, it is capable of forming large antigen-antibody complexes. In this manner, IgA neutralizes microbes and facilitates their removal by mucociliary clearance, inhibits microbial binding to epithelial cells, and inhibits uptake of potential allergens.

Selective IgA deficiency is defined as less than 7 mg/dL with normal values of IgM and IgG in patients 4 years old or greater. It is the most common primary immunodeficiency. The threshold of 4 years of age is used to avoid premature diagnosis of IgA deficiency, which may be transient in younger children due to delayed maturation of IgA production. Approximately 85% to 90% of patients with selective IgA deficiency are asymptomatic. Symptomatic individuals present with various manifestations including recurrent sinusitis, otitis media, pharyngitis, bronchitis, pneumonia, chronic diarrhea, and autoimmune syndromes. Patients with selective IgA deficiency are treated symptomatically for respiratory, gastrointestinal, and allergic problems. Since most preparations of intravenous immunoglobulin (IVIg) contain IgA, its use increases the risk of anaphylaxis if the recipient has anti-IgA antibodies. Transfusion of blood products presents a similar problem for these individuals. In patients with IgA deficiency and a history of anaphylaxis to IVIg products, it is recommended to consider an IVIg preparation with low IgA content or subcutaneous immunoglobulin.[73–75]

## Immunoglobulin G

Immunoglobulin G (IgG) is the most abundant antibody isotype in serum. It makes up 80% of the serum antibody levels and is the only one that can cross the placenta. It activates the complement cascade through the classical pathway. All IgG subclasses are found at the mucosal barriers at significant levels, and in some points, total mucosal IgG is the most abundant isotype, compared to secretary IgA amounts, such as in bronchoalveolar fluids. Mucosal IgG reaches the mucosal surface either being produced locally by mucosal plasma cells, or systemically, by the neonatal Fc Receptor

(FcRn). There are four subclasses of IgG (IgG 1 to 4) numbered by their amount in the serum and with differences based on the antigenic differences in structure of the heavy chain. However, in terms of effector functions, IgG3 has the highest effector capacity. IgG1 and IgG3 respond to protein antigens. They are T-dependent antigens; IgG2 and IgG4 respond to polysaccharide antigens, which are T-independent antigens. IgG functions by opsonizing microbes for phagocytosis and killing, activating the complement cascade, and neutralizing many bacterial endotoxins and viruses. Selective IgG deficiency is associated with upper respiratory tract infections.

Common variable immunodeficiency (CVID) is defined as significantly low levels of IgG in addition to one of isotypes IgA or IgM and poor vaccine response after test vaccination. The clinical phenotype is heterogeneous and is associated with recurrent otitis media, sinusitis, bronchitis, and pneumonia along with multiple autoimmune features and malignancy. Recurrence of airway infections may result in chronic airway injury with bronchiectasis. The combination of altered opsonic activity and bronchiectasis results in chronic colonization with respiratory pathogens such as *Pseudomonas aeruginosa.*

In patients suspected of IgG deficiency, quantification of IgG subclasses should be performed in addition to measurement of the antibody response to polysaccharide vaccines *(Streptococcus pneumoniae, Haemophilus influenzae).* IgG-deficient patients with recurrent respiratory tract infections often benefit from prophylactic antibiotics, immunoglobulin replacement, and the use of airway clearance techniques. X-linked agammaglobulinemia is characterized by low levels of all antibody isotypes due to a mutation in the Bruton's tyrosine kinase gene, which leads to a block in maturation of the B cell. Children with this disease uniformly develop chronic airway infection and lung dysfunction unless treated aggressively with supportive measures and immunoglobulin replacement.[76,77]

## Immunoglobulin E

Of the five antibody isotypes, serum immunoglobulin E (IgE) has the lowest concentration in humans due to the high affinity of mast cells for IgE. While other immunoglobulins require an antigen/antibody complex to bind to the cell bound Fc receptor (FcR), IgE does not require an antibody to bind to the FcR. IgE serves to protect via mast cell degranulation, which induces multiple functions, such as sneezing, coughing, emesis, and diarrhea, to expel pathogens (largely helminth parasites). It also can induce an antibody-dependent, cell-mediated cytotoxic response against helminthes. It binds to the parasites, and eosinophils then bind to the opsonized organisms via the IgE FcR. Eosinophils are then stimulated to release granular contents, resulting in lysis of the parasite. IgE also has a pathologic, central role in hypersensitivity reactions in response to benign allergens (antigens).

The hyper IgE syndromes (HIES) are characterized by elevated IgE levels, recurrent skin infections, eczema, and pulmonary infections. Many genetic defects have been identified, and the best elucidated are the mutations in the signal transducer and activator of transcription 3 (STAT3) gene, which is an autosomal dominant disease; mutations/deletions in dedicator of cytokinesis 8 (DOCK8); and tyrosine kinase 2 (TYK2) with the last two inherited as autosomal recessive defects. In STAT3 HIES, mucocutaneous candidiasis, sino-pulmonary infections with development of bronchiectasis and pneumatoceles, and associated facial and bone abnormalities are noted. In patients with DOCK8, sino-pulmonary infections are common, but pneumatoceles have not been described. Treatment relies on supportive measures, including IVIg, although there is a growing body of evidence to suggest hematopoietic stem cell transplant is beneficial for those with DOCK8 mutations. Isolated IgE deficiency has not been reported.[78,79]

## Immunoglobulin M

Immunoglobulin M is the first antibody isotype to be synthesized, and it is the first antibody produced in response to a foreign antigen. It is mostly found in the bloodstream, although mucosal IgM has been noted in physiologic amounts. It has been hypothesized that it provides a level of protection in those patients with selective IgA deficiency who are asymptomatic.

IgM gains access to the airway by exudation or by active secretion via the SC. IgM is capable of agglutinating bacteria and activating the complement cascade, with a greater efficiency compared to IgG due to an increased number of binding sites.

Both selective IgM deficiency and hyper-IgM have been highly associated with recurrent upper and lower respiratory infections. In selective IgM deficiency, the genetics is not well known, although it has been hypothesized that there is a functional defect in B cell differentiation prior to the secretion of IgM. Recurrent sino-pulmonary infection is the most common manifestation, up to 65% in one cohort.[80]

Hyper IgM syndromes are a group of disorders defined by a class switching defect involving the CD40 ligand/CD40 signaling pathway. The loss of this signaling leads to impairment of isotype switching and is characterized by an elevated IgM level with normal levels of IgG, IgA, and IgE. Clinical manifestations depend on the type of specific defect. Defects at the CD40 ligand or CD40 interrupt the costimulatory cross talk between CD 4+ T cells and B cells. In patients with defects in CD40 ligand (inherited as an X-linked disease, X-HIGM), patients can develop recurrent sino-pulmonary infections, including opportunistic infections such as *Pneumocystis jiroveci,* within the first 2 years of life. Data from international registries document that 81% of patients with X-HIGM develop pneumonia, with 65% of these being Pneumocystis jirovecii pneumonia (PJP).[81]

## Role of Programmed Cell Death and "Clearing the Garbage" in Lung Homeostasis

During the course of lung development, growth, and injury repair, cells must be replaced in orderly processes controlling the breakdown and turnover of internal contents (autophagy), cell death (apoptosis, necroptosis, ETosis), and removal of dead or dying cells (efferocytosis) to help preserve lung structure and function and prevent lung injury. In acute lung injury (ALI) and chronic lung diseases (such as CF), there is evidence that disordered programmed cell death and removal of dead cells result in ongoing inflammation and lung injury. While detailed description of these processes is beyond the scope of this chapter, a brief description of their role in lung homeostasis and repair is provided here.

**Autophagy** is an evolutionally conserved process present in virtually all eukaryotic cells. It is responsible for regenerating metabolic precursors and clearing subcellular debris, thereby maintaining cellular homeostasis. Autophagy involves the sequestration of regions of the cytosol or organelles within double-membrane–bound compartments and the delivery of these compartments to the lysosome for degradation. Autophagy is important in the "recycling" of cell components for reuse in a starvation state and is a key component of innate immunity: leading to the elimination of intracellular pathogens and processing antigens for presentation to lymphocytes. Impaired autophagy can result in accumulation of materials in the cell, leading to cell and tissue dysfunction. It is a highly regulated process that can be divided into three stages: initiation, execution, and maturation.[82,83] Initiation of autophagy is regulated by target of rapamycin (TOR) kinase that functions as an inhibitor or by alternative pathways that require activation of trimeric G proteins and class III phosphoinositide 3-kinases. Execution of autophagy involves conjugation pathways and complex formation that require autophagy gene (Atg) products. The maturation step involves fusion of these complexes with endosomal vesicles containing **l**ysosome-**a**ssociated **m**embrane **p**roteins (LAMP1 and LAMP2). These structures fuse with the lysosomes and acquire cathepsins and acid phosphatases to form autolysosomes.[82,83]

**Apoptosis** is one form of programmed cell death. Morphologically, apoptosis is characterized by nuclear shrinkage and formation of apoptotic bodies, keeping the cell membranes intact. Apoptotic cells are characterized by caspase activation, DNA fragmentation, and externalization of phosphatidyl serine onto the cell surface in a process dependent on caspase 3 activation. Seven of the 13 distinct human caspase genes are suggested to participate in apoptosis as initiator caspases (caspase-2, caspase-8, caspase-9, and caspase-10) or effector caspases (caspase-3, caspase-6, and caspase-7) that cleave a wide array of proteins that contribute to the structural or bioenergetic integrity of the cell (https://www.youtube.com/watch?v=9KTDz-ZisZ0). The initiator caspases can be activated by a series of polyprotein complexes, and each is activated in response to particular death signals. Apoptosis can occur through convergent extrinsic or intrinsic pathways. The *extrinsic pathway* involves cell surface death receptors belonging to the tumor necrosis factor-receptor (TNF-R) family (including TNF-R1, Fas/CD95, Death Receptor 3 [DR3], DR4, DR5, and DR6). These receptors are characterized by an intracellular death domain (DD) that transmits the apoptotic signal and leads to the formation of a complex of the death receptor, adaptor protein, and procaspase 8 (called the *death inducing signaling complex*), which leads to the autoproteolytic cleavage of procaspase 8 to caspase 8. The intrinsic pathway is induced by the stimulation of the mitochondrial membrane and translocation of the bcl2 family of proteins within the mitochondrial membrane, altering mitochondrial membrane permeability. This increased permeability results in the release of cytochrome c and other factors into the cytoplasm, where they recruit a caspase adaptor molecule (APAF1) and the apoptosis initiator enzyme procaspase 9. Cytochrome c, APAF1, procaspase 9, and ATP form a complex called the *apoptosome,* and procaspase 9 becomes activated to caspase 9. At this point, both intrinsic and extrinsic pathways converge into a common pathway, leading to activation of executioner caspases 3, 6, and 7.[84,85]

**Efferocytosis** is the process of removal of apoptotic cells. This process is different from complement-induced or Fc$\gamma$-induced phagocytosis in that it involves both "professional phagocytes" (macrophages and DC) and other cell types (epithelial cells and fibroblasts).[86] Apoptotic cells are recognized by membrane alterations (the "eat me" signals) that include externalization of phosphatidylserine and calreticulin onto the cell surface. CD31 (platelet-endothelial cell adhesion molecule-1) functions as a co-ligand that enhances attachment and engagement of the "eat-me" signals. An array of receptors has been shown to be associated with efferocytosis, including the low-density lipoprotein receptor-related protein (LRP, CD91), Mer receptor tyrosine kinase, $\alpha v\beta 3$ integrins, scavenger receptors, CF44, CD14, and complement receptors 3 and 4.[87] Receptor binding results in cell activation and engulfment of the apoptotic target cell. Efferocytosis results in the removal of apoptotic cells before their membranes become permeable, thereby preventing release of toxic intracellular contents.[87]

During late stages of cell death, soluble components are released that serve as “find me” signals. Soluble innate PRR can contribute to the identification of the “eat me” signals on the apoptotic cell surface, bind to them, and serve to bridge the apoptotic cell with phagocytes, promoting efferocytosis, thereby limiting inflammation.[87] Impaired efferocytosis plays a role in CF and asthma.[86]

## Summary

The lung is continuously exposed to potential pathogens. The multilayered defenses provided by the intrinsic, innate, and adaptive systems protect the lung from invasion, limit inflammation, and repair lung injury. Although there is considerable overlap in the activities of these defenses, defects can result in recurrent infection, persistent inflammation, and lung injury.

# Bronchoscopy and Bronchoalveolar Lavage in Pediatric Patients

*Robert E. Wood PhD, MD*

Visualization of the interior of the body is often the most effective and efficient way to evaluate a patient's problem. As an old Chinese proverb says, “A picture is worth a thousand words.” Advances in endoscopic techniques and instrumentation have greatly enhanced the pulmonary specialist's ability to visualize the interior of the respiratory tract. This in turn has led to improvements in diagnosis and treatment.

Bronchoscopy—the visual examination of the airways—is usually performed for diagnostic purposes but is also useful for certain therapeutic maneuvers. Bronchoscopy may be performed with either rigid or flexible (fiberoptic) instruments depending on the particular needs of the patient and the skills and instrumentation available to the bronchoscopist. In general, most things that can be done with a rigid bronchoscope can be done with a flexible instrument and *vice versa.* However, there are some notable exceptions. For example, a rigid instrument cannot be passed around a curve into the apices of the lungs or very far into the peripheral bronchi, while a flexible instrument is quite unsuited for removal of aspirated foreign bodies from the lungs of children. For the most effective care of pediatric patients, both rigid and flexible instruments must be available, and there must be practitioners trained in the use of each type of instrument (although not necessarily the same person). In many patients, the combined use of both instruments may yield the most optimal result.

In addition to visualization, bronchoscopes also provide an effective means to obtain specimens from the lungs and airways. Tissue samples may be obtained by biopsy forceps, secretions can be aspirated from the airways, and bronchoalveolar lavage (BAL) yields samples of the fluid resident on the surfaces of the alveoli and distal airways. Bronchoscopy is primarily a clinical tool but is increasingly being used for investigational purposes as well. Although pediatric patients present special challenges (technical as well as ethical) to the investigative use of bronchoscopy, age alone is no contraindication to the use of bronchoscopy for research.[1]

Bronchoscopy involves the examination of at least part of the upper airway as well as the trachea and bronchi; this is especially true with (and an advantage of) flexible instruments. Rigid bronchoscopes are generally passed through the patient's mouth, while flexible bronchoscopes are generally passed through the patient's nose. Bronchoscopes may also be used to examine just the upper airway, although the high incidence of concurrent upper and lower airway lesions[2–4] makes it wise to examine both upper and lower airways unless there is a good reason not to do so.

# Instrumentation

## Rigid Bronchoscopes

The rigid (“open tube”) bronchoscope consists of a metal tube of appropriate diameter and length that is passed into the trachea and through which the operator may look and the patient may breathe. The instrument is not a *simple* metal tube; it is equipped to deliver anesthetic gasses and light to the distal tip.

The large open channel, through which instruments may be passed, is one of the major advantages of rigid bronchoscopes. However, visualization is challenging, especially when passing an instrument (such as a biopsy forceps). A major advance in bronchoscopic technique came with the development of the glass rod telescope.[5] This device yields exceptionally fine optical performance, and various instruments such as biopsy and grasping forceps have been designed specifically to work with the telescopes. Rigid bronchoscopes have holes in the side along the distal tip to allow ventilation of the contralateral lung when the bronchoscope is advanced into one main-stem bronchus.

The rigid bronchoscope must be an appropriate size for the patient. Therefore, a variety of instruments must be available to the pediatric bronchoscopist ranging in diameters from 3 to 7 mm or larger and in length from 20 to 50 cm. There must be a full range of telescope lengths and diameters for the different bronchoscopes. In addition, glass rod telescopes may be made with a prism on the distal end to facilitate observation of the upper lobes (typically, 30, 70, or even 120 degrees).

Likewise, the auxiliary instruments (e.g., biopsy or grasping forceps) must match the telescopes and/or bronchoscopes. A large variety of forceps and other devices has been devised for specialized purposes. Perhaps the most valuable are the “optical forceps,” which are matched with a glass rod telescope and allow the bronchoscopist to operate the forceps under close and direct visualization.

The nomenclature of bronchoscope sizes can be confusing. In general, rigid instruments are defined by the diameter of the largest instrument that will pass through the bronchoscope, while flexible bronchoscopes are defined by their outer diameter. For example, a 3.5-mm flexible bronchoscope will easily pass through a “3.5-mm” rigid bronchoscope.

## Flexible Bronchoscopes

The flexible bronchoscope is essentially a solid instrument composed of thousands of glass fibers that carry the light for illumination and the image. The tip of the instrument can be deflected to guide it into the desired path or location. Most flexible bronchoscopes have a small suction channel through which secretions may be aspirated, fluids may be delivered to the airways, or small flexible instruments may be passed.

The typical pediatric flexible bronchoscopes in use today are 2.8 mm in diameter and with a suction channel approximately 1.2 mm in diameter. Smaller instruments (2.2 mm) have no suction channel, and therefore have somewhat limited utility when there are secretions or blood in the airways; they also cannot be used to obtain diagnostic specimens. Larger instruments, ranging from 4.2 to 6.3 mm in diameter, are used in adults. These instruments have suction channels ranging from 2.0 to 3.2 mm in diameter.

In contrast to the rigid bronchoscope, through which the patient breathes (either spontaneously or by positive pressure); the flexible bronchoscope forces the patient to breathe around the instrument. Therefore, the instrument must be small enough not only to fit into the airway but also to allow the patient to breathe. Most infants as large as 1.5 kg can breathe spontaneously around the 2.8-mm bronchoscope, but great care must be taken to ensure the adequacy of ventilation during procedures.

Flexible bronchoscopes are quite limited in their capacity to accommodate instruments. The most common instruments used with flexible bronchoscopes are flexible biopsy forceps and cytology or microbiology brushes. Small grasping forceps and folding retrieval baskets are also available but have limited usefulness, especially in pediatric patients. Suctioning is done directly with the bronchoscope rather than by passing a device through the channel, as is the case with rigid bronchoscopes.

Flexible bronchoscopes are limited in their optical performance by the number of glass fibers, which conduct the image. While larger, adult-size instruments now mostly utilize a video chip at the working tip (and thus generate an image of much higher resolution), pediatric instruments, because of their small diameter, continue to rely on glass fibers to transmit the image. While the images obtained by flexible instruments are quite satisfactory for most clinical purposes, the glass rod telescopes and video scopes provide much greater resolution and image quality.

## Care and Maintenance of Bronchoscopes

Bronchoscopy is not a *sterile* procedure, since the instruments pass through a nonsterile area (the nose or mouth). However, bronchoscopes and associated instruments must be cleaned and sterilized before use in a patient.[6] Transmission of infectious agents from patient to patient due to inadequate cleaning or sterilization procedures has been well documented.[7,8] In general, bronchoscopic equipment should be cleaned as soon as possible after use, as dried blood or mucus is much more difficult to remove and will prevent adequate sterilization by any method.[9] At a minimum, the instruments should be flushed with water immediately after use and, if possible, soaked in an enzymatic detergent until formal cleaning can be done.

Rigid bronchoscopes are cleaned by vigorous brushing with detergent, followed by rinsing; they may be sterilized by steam autoclaving. Glass rod telescopes (unless specially marked) may not be exposed to steam, however, and must be sterilized with ethylene oxide or with liquid agents such as glutaraldehyde or peracetic acid.[10]

Flexible bronchoscopes are cleaned by careful scrubbing of the exterior with a soft cloth and enzymatic detergent. The suction channel must be cleaned by multiple passes of an appropriate cleaning brush. Thorough rinsing is followed by high-level disinfection[9,10] (with glutaraldehyde or peracetic acid) or sterilization (with ethylene oxide). Flexible bronchoscopes will melt in a steam autoclave…

The lenses of rigid telescopes and flexible bronchoscopes must be carefully scrubbed and polished with a soft cloth during cleaning. Otherwise, small amounts of protein left on the lens will accumulate over time, making the image progressively less satisfactory. Flexible bronchoscopes and glass rod telescopes are made of glass and are fragile (not to mention expensive). They must never be dropped and must not be subjected to forces that will cause breakage. Flexible bronchoscopes should never be passed through a patient's mouth unless protected by a rigid bite block, since an endotracheal tube will not protect the bronchoscope from severe damage by teeth. The care with which instruments are cleaned and handled must match the care with which they are utilized in the patient's airway. Individuals responsible for cleaning and preparing the instruments must be well trained and supervised.

# Techniques for Bronchoscopy

## Facilities for Bronchoscopy

It is important that bronchoscopy be performed in a suitable venue. Because of the need for general anesthesia, rigid bronchoscopy is almost always performed in an operating room. The relative ease with which flexible bronchoscopy can be done makes it tempting to use the instrument in unconventional places such as at the bedside or in an emergency room. However, while there are clearly circumstances in which such practice is justified, bronchoscopy is a serious procedure with the potential for lethal complications and should be performed only by physicians who are well trained, with the necessary cognitive and technical skills, and with full preparation for all contingencies. Therefore, a fully equipped and staffed endoscopy suite or operating room is the most appropriate venue. With suitable preparation, bronchoscopy (rigid or flexible) can be performed at the bedside in an intensive care unit, but this may still place the bronchoscopist at a disadvantage in terms of access to equipment and supplies in the event of difficulties. If bronchoscopy is performed in an intensive care unit, the bronchoscopist must take along everything that will possibly be needed and have it readily at hand.

## Rigid Bronchoscopy

The appropriate rigid bronchoscope (length and diameter) is chosen for the patient. Under a satisfactory level of anesthesia, the patient is positioned supine with the shoulders supported and the head slightly extended. The larynx is exposed with a laryngoscope and the tip of the bronchoscope is gently advanced through the glottis and into the trachea. With the proximal end of the bronchoscope closed with a lens cap or with a telescope in place, the side port is attached to the anesthesia circuit, and the patient can be ventilated with positive pressure.

The bronchoscope is manipulated to visualize the tracheal and bronchial anatomy; the head and neck may be turned to help direct the bronchoscope into the right or left main bronchi. Telescopes greatly facilitate inspection and can be used in conjunction with a video camera. Angulated telescopes make it much easier to visualize the upper lobe segments. The telescope must be removed and cleaned if the lens becomes covered with secretions; suctioning is performed with a suction pipe or a suction catheter. During these times, ventilation is momentarily interrupted. It is also possible to work for extended periods with an open proximal end while maintaining ventilation with a Venturi jet injector.

When instrumentation is required, such as for the removal of a foreign body, the instruments may be passed through the open channel of the bronchoscope. Unfortunately, this significantly impairs the view of the operative site, as the instruments obstruct the line of vision. Optical forceps, which incorporate the glass rod telescope and allow direct visualization of the operative site, is the preferred instrument for biopsy and for foreign body extraction. Very small flexible forceps can also be passed through a side arm and alongside the telescope, but the tips of these instruments may be difficult to control.

In our practice, at Cincinnati Children's Hospital, the vast majority of rigid bronchoscopic procedures (including foreign body removal) are performed using only the glass rod telescopes; the open tube sheath is employed in special circumstances. This technique requires that the patient breathe spontaneously, so anesthetic technique is critical, but it is much easier to evaluate airway dynamics. Because the overall size of the instruments is smaller, mechanical complications are less frequent.

## Flexible Bronchoscopy

Most diagnostic procedures in pediatric patients can be performed with the standard 2.8 mm or 3.5-mm pediatric flexible instruments. In older children, a small “adult” instrument may be used (especially if a larger suction channel is needed); while in very small infants, it may be appropriate to use a 2.2-mm ultrathin bronchoscope. The patient is properly prepared for the procedure and positioned supine with the head and neck in a neutral position. It is also possible to perform flexible bronchoscopy in a sitting or some other position in special circumstances.

Flexible bronchoscopes are usually inserted transnasally. This avoids the potential for the patient to bite (and thus destroy) the instrument and also affords a view of the nasal and nasopharyngeal anatomy. Another advantage of this approach is that the bronchoscope does not contact the tongue; the tongue is a very powerful muscle and can readily move the bronchoscope in ways contrary to the intent of the bronchoscopist. A flexible bronchoscope may also be inserted orally if desired, always with a suitable bite block, even with the patient under general anesthesia, or through an artificial airway such as an endotracheal tube (with a bite block), a tracheostomy tube or a laryngeal mask airway (LMA).

The tip of the flexible bronchoscope can be flexed or extended in a single plane; movement to one side or another is accomplished by rotation. The instrument is directed to the site of interest by advancing the shaft while controlling the angulation and rotation at the tip. This combination of three simultaneous movements requires good hand-eye coordination on the part of the bronchoscopist. In contrast to glass rod telescopes, the image rotates as the instrument is rotated; this may produce disorientation on the part of operators unaccustomed to using flexible instruments. As the instrument is advanced through the airway, secretions may be removed by suctioning, and topical anesthetic can be applied, also through the suction channel.

The patient must be able to breathe around the instrument; most infants 3 kg or larger can breathe satisfactorily around the 3.5-mm pediatric flexible bronchoscope (infants larger than about 1.5 kg can usually breathe around the 2.8 mm instrument). Smaller infants will not be able to do so, and their procedures must be performed with an ultrathin instrument or with an apneic technique. If the patient is intubated, the bronchoscope must be small enough to readily pass through the tube (Table 9.1).

**Table 9.1**

**Artificial Airways and Flexible Bronchoscopes Used in Pediatric Patients**

| **Instrument Diameter (mm)** | **Smallest Tube That Can Be Used (mm)**[a] | **Smallest Tube for Assisted Ventilation (mm)** | **Smallest Tube for Spontaneous Ventilation (mm)** |
|---|---|---|---|
| 2.2 | 2.5 | 3.0 | 3.5 |
| 2.8 | 3.0 (not recommended) | 3.5 | 4.0 |
| 3.5 | 4.5 | 5.0 | 5.5 |
| 4.2 | 5.0 | 5.5 | 6.5 |
| 4.9 | 5.5 | 6.0 | 7.0 |

[a] For intubation only.

Flexible bronchoscopes are much smaller than rigid instruments (although the glass rod telescopes, if used alone, are equally small) and can be advanced much farther into the distal airways. Depending on the instrument used and the size of the patient, airways as small as 2 mm and as far as 14 to 16 generations from the carina may be inspected.

The instruments that can be passed through a flexible bronchoscope are quite limited, because of the small diameter of the suction channel (1.2 mm in pediatric instruments, 2.0 to 3.2 mm in “adult” instruments). Cup or “alligator” biopsy forceps, brushes, grasping forceps, expandable basket retrieval devices, balloon catheters (for dilation of stenoses), monopolar electrodes, and laser fibers are the most common such instruments.

## Anesthesia for Bronchoscopy

Safe and effective bronchoscopy requires that the patient be comfortable and reasonably still during the procedure. Adequate oxygenation and ventilation must be maintained, and the patient must be carefully and continuously monitored. These criteria can be met with either general anesthesia (administered by an anesthesiologist) or with sedation (usually performed by the intravenous administration of a narcotic and/or a benzodiazepine,[11] and administered by the bronchoscopist or sedation nurse) depending on the individual child's situation and the procedure planned. Sedation and general anesthesia are merely points on a continuum between the fully awake state and surgical anesthesia; it matters little how the desired, safe state is achieved. Deep sedation and light “general anesthesia” are virtually indistinguishable. An advantage of general anesthesia is that an anesthesiologist takes full responsibility for monitoring the patient. Current practice guidelines for sedation[12] mandate the presence of a trained individual whose sole responsibility is to monitor the patient, although this person does not have to be an anesthesiologist. Our current practice at Cincinnati Children's Hospital is to utilize an anesthesiologist, and the child is sedated with general anesthetic agents (inhaled or given intravenously) to a point that maintains spontaneous breathing but ensures safe comfort. A significant advantage of using “general anesthetic” agents for sedation is rapid induction and relatively rapid emergence, as well as the ability to quickly change the degree of sedation (and therefore respiratory effort) during the procedure.

Sedation and anesthesia diminish or abolish protective reflexes. To reduce the risk for aspiration of gastric contents, patients should be given nothing by mouth for several hours prior to the procedure. Clear liquids may be given up to 2 hours before the procedure. It is prudent to aspirate the stomach with a catheter before proceeding with the bronchoscopy. Young infants may become dehydrated or hypoglycemic if kept NPO for too long, and intravenous fluid may be necessary prior to a procedure.

When general anesthesia is utilized for diagnostic bronchoscopy, careful attention must be given to airway dynamics. If the patient does not breathe spontaneously, then the usual airway dynamics are reversed—airway pressure during inspiration exceeds that during expiration. This may result in diagnostic confusion in patients with tracheomalacia and/or bronchomalacia. During therapeutic procedures, deeper anesthesia and positive-pressure ventilation are often utilized.

Flexible bronchoscopes are small enough that the patient can usually breathe around them. Spontaneous breathing is the rule for most flexible procedures. Oxygen can be supplied through an oral airway or a mask. Many practitioners routinely utilize an LMA; this, while providing a secure airway, requires deeper sedation, eliminates the ability to evaluate the anatomy and dynamics of the upper airway, and may mask tracheomalacia or bronchomalacia. It is therefore not recommended as a routine practice.

Sedation, similar to general anesthesia, may be produced by a variety of agents and techniques. Important principles of sedation include careful preparation of the patient, the use of fractional doses of relatively short acting agents with titration of total dose to the needed effect, appropriate monitoring before, during, and after the procedure, and careful selection of agents.

Sedative/anesthetic agents have a variety of physiologic effects in addition to reducing the level of consciousness. The most important of these is depression of respiratory drive, and this effect may last longer than the sedation. Children who have undergone sedation for procedures may be at greater risk after the procedure is completed than during the procedure itself, as there is no longer the stimulation of the procedure, and staff awareness and alertness may be diminished. Effective monitoring must be continued until all the effects of sedation have resolved.

Pharmacologic agents to reverse the effect of narcotics and benzodiazepines are available, and some physicians have utilized these agents routinely at the completion of procedures. This is not necessarily a good idea, however, as their effect is considerably shorter than the respiratory depression induced by the sedative agents. Furthermore, patients awakened abruptly from sedation are often disturbed and may become combative. Monitoring must be continued regardless of whether a reversal agent has been given; indeed, it may be argued that monitoring must be continued longer after reversal than without it. On the other hand, such agents should always be readily available in the event of serious respiratory depression.

Sedation—no matter how administered—involves more than giving drugs. Children are often very responsive to suggestion—whether positive or negative, whether intentional or inadvertent. Simple distraction or more formal methods of focusing attention on something other than the procedure[13,14] may be surprisingly effective in children, especially in the 3- to 8-year age group. Even infants respond to tone of voice and the atmosphere around them. Careful preparation of the child and the parents, focusing on positive aspects and creating positive expectations can be powerful adjuncts to chemical sedation. On the other hand, negative suggestions can make even the most powerful drugs less effective. A screaming, upset child will require much higher doses of virtually any agent to achieve effective sedation, and that child's recovery will be prolonged. For this reason, presedation with oral drugs such as midazolam and careful attention to atmosphere and language can often facilitate deeper sedation with minimal doses of other agents.

Airway management during bronchoscopy can be a challenge. The anesthesiologist must understand the goals of the procedure and enable the bronchoscopist to accurately evaluate not only the anatomy, but also the dynamics of the upper and lower airways. During evaluation of the upper airway, it is best to have a native airway with no devices or support, as in many pediatric patients, the diagnostic finding of most interest is dynamic obstruction of the upper airway. Once this has been evaluated, an oral airway can be placed to secure the upper airway, and oxygen and anesthetic gas can be delivered through an endotracheal tube inserted into the oral airway (Fig. 9.1). After the tracheal and bronchial dynamics have been evaluated, then if necessary, the bronchoscope can be removed and an LMA or endotracheal tube can be used for the remainder of the procedure.

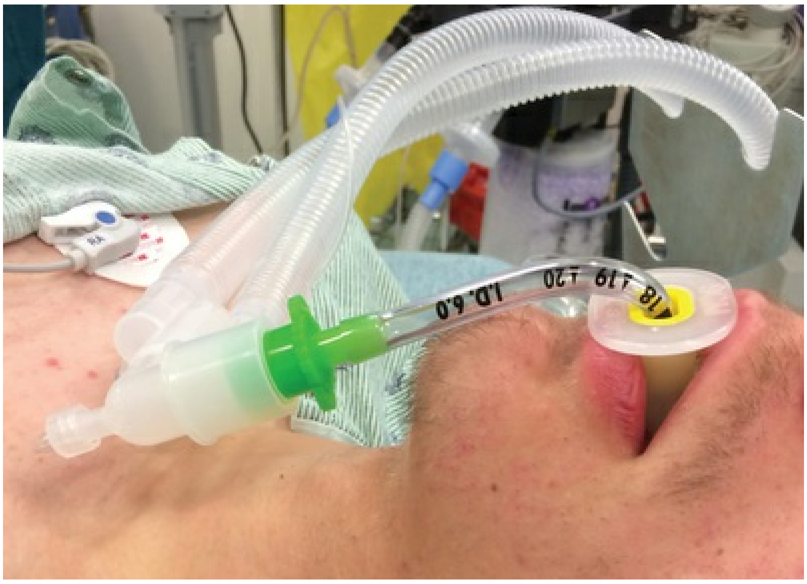

**FIG. 9.1** Oral airway for delivery of oxygen and anesthetic gas during flexible bronchoscopy.

## Indications for Diagnostic

# Bronchoscopy

It is difficult to categorize the indications for diagnostic bronchoscopy without a great deal of overlap. In a given situation, there is often more than one indication for bronchoscopy (for example, a child with recurrent pneumonia may also be suspected of aspiration). In general, however, one may utilize a bronchoscope to define airway anatomy and airway dynamics, and to obtain specimens for further diagnostic study. The diagnostic result of a particular procedure may include anatomic findings, definition of airway dynamics, and the results of microbiologic and/or microscopic evaluation of specimens obtained during the procedure. Bronchoscopy performed for diagnostic purposes may also have therapeutic benefit, such as the removal of a mucus plug causing atelectasis.

It should be noted that there is often great value in a normal bronchoscopic examination; the definitive exclusion of suspected problems (such as foreign body aspiration, for example) may be as important as a specific diagnostic finding. Bronchoscopy (rather than simple laryngoscopy) is often performed in patients in whom the suspected lesion is in the upper airway. Since effective laryngoscopy in children usually requires sedation and laryngeal anesthesia, it adds very little to the risk of the procedure to continue the examination into the lower airways. Unsuspected lesions in the lower airways are not uncommonly found,[3,15] even in patients in whom significant pathology, explaining the patient's symptoms, is seen at or above the glottis.[2]

Airway obstruction is one of the most common general indications for diagnostic bronchoscopy, and may involve the upper or lower airways or both. The extent of anatomic obstruction, especially fixed obstruction in the subglottic space, is often much greater than would be suspected from clinical examination. If a patient is stridulous during the examination, the vibrating structures causing the noise will *always* be visible, if one is looking in the right place.

Imaging techniques, such as CT or MRI scans, can yield considerable diagnostic information about the lungs and airways. In some cases, such techniques may make bronchoscopy unnecessary. However, imaging studies are quite limited and cannot provide specimens or (in most cases) adequately define abnormal airway dynamics. In general, radiologic studies should be performed prior to bronchoscopy, as it may be important to direct the focus of the bronchoscopy (e.g., BAL site) to a specific region of the lungs. In general, there is only one indication for diagnostic bronchoscopy—there is information in the lungs or airways necessary to the care of the patient, which is best obtained by bronchoscopy (Table 9.2).

## Table 9.2

## Indications for Diagnostic Bronchoscopy

| Indication | Rigid Instruments | Flexible Instruments |
|---|---|---|
| Stridor | May alter airway dynamics | Preferred |
| Persistent wheeze (not responsive, or poorly responsive to bronchodilator therapy) | | Preferred |
| Atelectasis (persistent, recurrent, or massive) | May be needed to remove airway obstruction | |
| Localized hyperinflation | | Preferred |
| Pneumonia<br>▪ Recurrent<br>▪ Persistent<br>▪ Patients unable to produce sputum<br>▪ Atypical or in unusual circumstances (e.g., immunocompromised patients) | | Preferred (much better to obtain BAL specimens) |
| Hemoptysis | May be best if there is brisk bleeding | Preferred to evaluate distal airways |
| Foreign body aspiration<br>▪ Known<br>▪ Suspected | Mandatory for removal of foreign bodies | May be useful to examine for the possibility of foreign body; rarely useful for removal |
| Cough (persistent) | | Preferred |
| Suspected aspiration | Preferred to evaluate posterior larynx and cervical trachea | Preferred to obtain BAL |
| Evaluation of patients with tracheostomies | Preferred to evaluate posterior larynx and subglottic space | Preferred to evaluate tube position and airway dynamics |
| Suspected mass or tumor | Preferred for laryngeal or tracheal lesions | Preferred for lesions in distal airways |
| Suspected airway anomalies | | |
| Complications of artificial airways | | |

*BAL*, Bronchoalveolar lavage.

Care must be taken to ensure that airway dynamics are not altered by positive-pressure ventilation, which will often prevent dynamic airway collapse. The depth of sedation may also influence airway dynamics; if the patient is too deeply sedated, abnormal dynamics may not be visible, as they are dependent on the transmural pressure gradients generated by breathing.

The choice between rigid and flexible instruments should be made with some care if there is a choice available. In many patients, the *combined* use of *both* rigid and flexible instruments can add immeasurably to the value of the procedures. Rigid instruments often distort the airway, while at the same time allowing better visualization of anatomic details. This is especially true in the larynx and upper trachea. Rigid instruments lift the mandible and hyoid but allow for a much better view of the posterior aspects of the larynx and cervical trachea. Flexible instruments produce little or no anatomic distortion (they follow the natural curvature of the airway), but they approach the larynx *from behind* and are therefore less capable of viewing details of the posterior aspects of the larynx, subglottic space, and cervical trachea (Fig. 9.2).

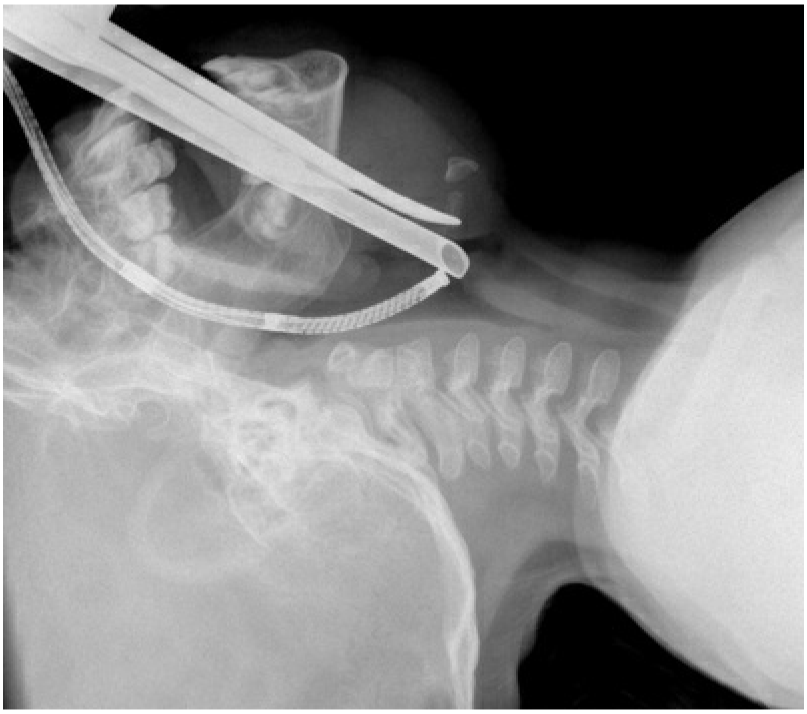

**FIG. 9.2** The rigid bronchoscope approaches the

larynx directly, with mandibular lift. The flexible instrument approaches the larynx from behind, making it difficult to evaluate the subglottic space and posterior cervical trachea.

## Contraindications to Bronchoscopy

Bronchoscopy should not be performed in the absence of a suitable indication or appropriate equipment and personnel skilled in its use. Otherwise, there are no absolute contraindications to bronchoscopy. However, if the same diagnostic information can be obtained by a less expensive, less invasive, or potentially less dangerous technique, then bronchoscopy is not indicated.

Relative contraindications to bronchoscopy include any factor that will increase the risk. Specific risk factors should be treated and if possible alleviated prior to bronchoscopy. Cardiovascular instability, bleeding diatheses (thrombocytopenia or hypoprothrombinemia), severe bronchospasm, and hypoxemia are primary examples. Some conditions that increase the risk are themselves indications for bronchoscopy, such as severe airway obstruction. In these cases, the procedure is performed with both diagnostic and therapeutic intent and can be lifesaving. Appropriate modifications must be made in the techniques chosen for anesthesia and monitoring when there are additional risk factors.

## Bronchoalveolar Lavage

There is more to bronchoscopic diagnosis than meets the eye. BAL[16,17] yields a specimen that can give representative data from the distal airways and alveolar surfaces and has become one of the more important aspects of diagnostic bronchoscopy. BAL may be defined as the instillation into and recovery from the distal airways of a volume of saline sufficient to ensure that the fluid returned contains at least some fluid that was originally present on the alveolar surface. Both soluble and cellular constituents of the alveolar (and small airway) surface fluid are contained in the effluent. This epithelial surface fluid is diluted to an unknown but significant degree by the saline used in its collection. Therefore, the concentrations of substances measured in the BAL fluid do not give an accurate estimate of the concentration at the epithelial surface. Various methods have been employed to derive a reasonable measure of the dilution,[18] although none are free of problems since the epithelial fluid is not static. There is constant flux of fluid and soluble constituents across the epithelial surface, and the duration and volume of the fluid employed for lavage may have substantial impact on the concentration of substances in the effluent.[19] Fortunately, for clinical purposes, and especially in pediatric patients, the information in most cases need not be quantitative. The primary value of BAL is to obtain a specimen from the distal airways that is relatively representative, and which can yield information about infectious and/or inflammatory processes. However, the interpretation of BAL data is rarely totally free of ambiguities.

## Indications for Bronchoalveolar Lavage

BAL is performed primarily for diagnostic purposes, although it can also be performed for therapeutic reasons. The main indications are listed in Box 9.1. BAL may be indicated for the diagnosis of infectious processes when a sputum specimen cannot be obtained or when the results from sputum analysis are equivocal. In immunocompetent individuals, this may include the infant or young child with cystic fibrosis with pulmonary symptoms requiring therapy. These children may be unable to produce sputum spontaneously, and cultures from the upper airway may either yield no pathogens when the bronchi are infected or yield pathogens when the lungs are sterile. In immunocompromised individuals with pulmonary infiltrates, the diagnosis of potential infections is often impossible except by BAL.[20,21] In either immunocompetent or immunocompromised individuals, BAL may help to distinguish infectious from noninfectious processes in the child with radiographic abnormalities. In general, however, if a satisfactory sputum specimen can be obtained, bronchoscopy solely to obtain cultures from the distal airways is not indicated as a primary approach. It may, however, be indicated when therapy geared towards suspected pathogens based on a sputum sample fails to provide therapeutic response. BAL should ideally be performed before antimicrobial therapy is started, but BAL may still be informative if there is a lack of clinical response or clinical deterioration.

**Box 9.1**

## Indications for Bronchoalveolar Lavage

Diagnosis of suspected infection
Evaluation for aspiration
Pulmonary infiltrates
Dyspnea
Hypoxia
Tachypnea
Recurrent pulmonary infiltrates
Persistent pulmonary infiltrates
Interstitial infiltrates
Diffuse alveolar inflammation
Pulmonary hemorrhage
Alveolar proteinosis
Pulmonary histiocytosis
Aspiration
Lung transplant
Hypereosinophilic lung diseases
Therapeutic removal of materials

BAL is often helpful to distinguish infectious from noninfectious processes, such as alveolar hemorrhage (which may occur without frank hemoptysis), pulmonary alveolar proteinosis, histiocytosis, or interstitial lung diseases. BAL is also indicated in the evaluation of patients with suspected aspiration, both to obtain microbiologic specimens to guide antibiotic therapy and to obtain evidence of the aspiration. Although a specific exogenous marker is not available, the presence of significant numbers of macrophages heavily laden with lipid[22] is a strong correlate of aspiration. “Soft” markers for aspiration of oral secretions include large numbers of oropharyngeal flora and squamous epithelial cells. In patients who have undergone lung transplant, BAL is often used in conjunction with transbronchial biopsy (TBBX) to distinguish rejection from infection.[23] BAL alone, however, is not sufficient to establish a diagnosis of rejection in these patients.

In addition to diagnostic indications, BAL is occasionally indicated for the therapeutic removal of materials from the airway. This may include the removal of mucus plugs or blood clots, the removal of bronchial casts in plastic bronchitis, or whole lung lavage as a therapy in pulmonary alveolar proteinosis. Additionally, BAL may be therapeutic for the removal of foreign lipoid material from the lungs.

## Techniques for Bronchoalveolar Lavage

BAL is most conveniently performed during flexible bronchoscopy. Care must be taken to avoid contamination of the lower airway specimen with upper airway secretions during passage of the bronchoscope through the upper airway (or by aspiration following topical laryngeal anesthesia). For routine procedures, it is helpful to gently suction away excessive nasal and oral secretions before inserting the bronchoscope and to flush oxygen through the suction channel (flow ca 2 L/min) while passing the bronchoscope through the upper airway. Excessive volumes of topical anesthetic should be avoided. In a supine patient, there is a 30-degree downhill slope from larynx to carina, and as soon as the larynx is anesthetized, oral secretions may begin to flow towards the carina. For this reason, suction should not be performed through the bronchoscope until the tip of the instrument is deep within the lungs. It is helpful to preselect the BAL site and to perform the BAL as soon after entering the trachea as possible to minimize the chance of aspirating significant volumes of oral secretions into the specimen. In immunocompromised patients or those in whom it is vital to minimize ambiguity in the results, it is useful to electively intubate the patient and pass the flexible bronchoscope through the endotracheal tube or to use a laryngeal mask. The upper airway can be examined later after removing the endotracheal tube. In children who already have a tracheostomy tube in place, performing BAL through the tracheostomy tube prior to examining the upper airway may lead to less contamination.

After the bronchoscope has been introduced into the lower airway, it should be gently wedged into the selected bronchus. Site selection is based on clinical, bronchoscopic, or radiographic findings. If there is diffuse disease, however, it is advantageous to wedge the bronchoscope into the lingula or right middle lobe bronchus (although in suspected aspiration, dependent bronchi may be more appropriate).

With the bronchoscope gently wedged into the bronchus, sterile normal saline is instilled through the suction channel of the bronchoscope and immediately withdrawn. Enough air should be instilled after each aliquot to ensure clearance of the saline from the suction channel. The volume of the channel can be as high as 2 mL in bronchoscopes with larger suction channels. The fluid may be withdrawn by hand suction with a syringe, or may be aspirated into a trap. Although enough suction must be applied to overcome the resistance of the channel in the bronchoscope; too much negative pressure will cause the bronchus to collapse, preventing efflux of fluid and possibly causing trauma to the airway mucosa. Fluid return may also be impaired if the patient is not breathing spontaneously. In some patients, almost any amount of negative pressure will result in collapse of the bronchus, and fluid return may be challenging. In such situations, it may be necessary to instill additional volumes of saline to recover a representative specimen. The suction port at the tip of a flexible bronchus is offset from the optical axis of the instrument so that if the bronchus into which the instrument is wedged is centered in the image, the suction port may be partially occluded by the bronchial wall. Positioning the bronchoscope so that the image of the bronchus is off center may improve fluid return.

Some centers utilize saline that has been warmed to body temperature (37°C) (supposedly to minimize bronchospasm and increase return), although with small volume BAL, there is little risk, and room temperature saline may be safely used. There is no consensus as to the number and volume of aliquots that should be used in BAL. In adult patients, it is common to utilize three aliquots of 100 mL or five aliquots of 50 mL. In children, various protocols have been used. Some bronchoscopists use a standard volume of 10 to 20 mL in 2 to 4 aliquots regardless of body weight and age; others adjust the volume to the patient's FRC based on weight or adjust the volume based on weight using 3 mL/kg divided into three aliquots with a maximum of 20 mL per aliquot.[24] Given the great variability in alveolar surface area being sampled based on the child's size, the size of the bronchoscope, and the location of the wedge, no BAL technique is truly capable of standardization. Smaller bronchoscopes will pass further into the distal airways before wedging, and each bronchial division cuts the lung volume that is sampled by at least half. For clinical purposes, the precise volume is probably of little relevance, as the primary application in children is the detection of infectious agents and examination of the cellular constituents. There should be reasonable uniformity in technique within a given institution. For clinical research, consistent protocols may be helpful, but no technique will ensure that the dilution of specimens is truly uniform.

Generally, 40% to 60% of the instilled fluid will be recovered, and the remainder of the fluid will be absorbed over a few hours. The first aliquot returned is relatively enriched in fluid from the surface of the conducting airways and may have a higher percentage of neutrophils.[25] Some bronchoscopists therefore separate out this first aliquot for culture rather than pooling it with subsequent aliquots, although the bronchial surface fluid will be washed into the alveolar spaces by each aliquot, therefore “contaminating” the subsequent aliquots with bronchial contents. For routine purposes, the small differences in content from one aliquot to the next do not warrant different handling.

Performing a BAL usually prolongs the bronchoscopic procedure by 1 to 3 minutes, minimally increasing the risks of hypoxia or hypercarbia, but is well tolerated by most patients, even those who are critically ill. If a patient is thrombocytopenic, BAL could theoretically increase the risk of bleeding, but can be performed relatively safely in children with platelet counts greater than 20,000 platelets/mL.[26] Some children do develop transient fever after BAL, especially if their airways were significantly inflamed, but this is almost always transient and self-limited. A theoretical risk of spreading infection and causing iatrogenic pneumonia exists,[7] but is rarely proven. The most problematic complication of BAL is not obtaining the correct information by not preparing for and adequately performing the procedure, or by failing to perform the appropriate analysis of the specimen.

An extension of BAL is whole lung (“bronchopulmonary”) lavage that is used therapeutically in individuals with pulmonary alveolar proteinosis. Alveolar proteinosis is less common in children than adults, and special techniques may be required for whole lung lavage.[27] Whole lung lavage can be performed with partial cardiopulmonary bypass or by sequential single lung lavage. In children with pulmonary alveolar proteinosis, multiple whole lung lavages are usually needed over a prolonged period (years) so that the use of bypass is quite problematic. I have successfully performed sequential (single) whole lung lavage on infants as small as 3.5 kg.[28]

Another special technique is nonbronchoscopic BAL.[29] This involves blindly placing a catheter through an endotracheal or tracheostomy tube into a distal “wedged” position, instilling normal saline and then withdrawing that saline into a trap or syringe. The suction catheter should have only one hole at the end. This is truly a blind procedure and will likely only yield useful results in diffuse lung disease. Some groups have advocated use of this technique routinely in neonates intubated with small endotracheal tubes. However, the wide availability of a 2.8 mm flexible bronchoscope that can be used through endotracheal tubes as small as 3.5 mm has significantly decreased the need for nonbronchoscopic procedures.

## Processing of Bronchoalveolar Lavage Specimens

BAL fluid should be processed promptly. Some centers keep the sample at 4°C prior to processing to maintain cell viability,[16] although this is most important if the sample will not be promptly transported to or processed by the laboratory and is not generally necessary. The sample should routinely be processed for microbiology and cytological studies. Some research protocols call for filtering of the BAL fluid prior to processing (to remove mucus plugs, etc.). However, this procedure may alter the diagnostic value of the specimen, as cells and microorganisms may adhere to the filter, and there may be important information hidden within mucus plugs. The bronchoscopist should organize a routine technique for processing with the institutional laboratory service; pediatric specimens require different processing and interpretation than do specimens from adult patients.

Microbiologic studies are performed according to the clinical indications for the procedure. Because of the potential for contamination of BAL specimens by secretions from the oropharynx, semiquantitative culture techniques may help in the interpretation of results. Large numbers of “oral flora” may indicate contamination of the specimen with oral secretions (or may be a reflection of aspiration of oral secretions prior to the procedure). In addition to cultures, other techniques such as special stains or PCR may help to identify pathogens; the bronchoscopist should consult with the laboratory to determine what analyses may be available and the specific requirements for specimen volume and handling.

The basic cytological analysis of a BAL specimen involves a cellular differential, which can be performed with simple stains such as Wright's or Giemsa. The specimen is centrifuged onto a slide; most centers perform cytospins at 250 to 500 × g for 5 to 10 minutes. Special stains are performed according to the clinical indications (e.g., lipid or iron stains and methenamine-silver stains). Differential cell counts are more useful than total cell counts, because of the variable dilution of the specimen. A hypocellular specimen (defined either by cell count or observation of the stained slides) may indicate an inadequate specimen, and the data from such specimens should be interpreted with caution. Flow cytometry can be done for special indications.

Although all BAL samples should routinely be processed for microbiologic studies and cytology, there is wide variability in practice as to the specific tests that are considered routine. This variability stems from differences in patient population, in institutional capabilities and preferences, and in advancing technologies. Box 9.2 lists some potential analyses for BAL fluid.

Cytokines

## Interpretation of Bronchoalveolar Lavage Findings

Interpretation of BAL findings must be undertaken with the knowledge that both technique and disease state play a large role in results. For instance, wedging more proximally increases both cell number and percentage of neutrophils. Small volumes sample mainly the airway. BAL samples the bronchial and alveolar surfaces and does not necessarily reflect parenchymal processes. In general, cell numbers in normal children will range between 100,000 and 250,000 cells/mL. Normal BAL fluid contains less than 5% neutrophils (usually 1% to 2%).[30,31] Patients with an active bacterial infection may have up to 95% neutrophils, and rarely less than 25%. Patients with bacterial infection often have bacterial forms visible in the cytoplasm of neutrophils recovered in BAL[32]; this may be a useful measure to differentiate between infection and contamination of the specimen with oral secretions. Increased neutrophils can also be seen in chronic inflammatory states associated with aspiration or cystic fibrosis, in ARDS, in alveolitis, in scleroderma, and even in asthma. Normally, 80% to 90% of the nonepithelial cells in BAL are alveolar macrophages. Lymphocytes are the next most common cell type, comprising 5% to 10% of the BAL cells in normal children. Although increased percentages of lymphocytes are not diagnostic of any specific disease, increased numbers are seen in interstitial lung disease such as hypersensitivity pneumonitis or sarcoidosis and mycobacterial infection. Eosinophils are rare in normal subjects (0% to 1%); significant numbers suggest an allergic state, eosinophilic pneumonia, parasitic infection, interstitial lung disease, drug-induced lung disease, *Pneumocystis jirovecii* infection, or a foreign body reaction. Very high numbers are seen in eosinophilic pneumonia. Epithelial cells are common in BAL fluid but are not counted in the differential. Squamous cells from the upper airway, often covered in oral bacteria, and ciliated columnar cells from the lower airway can also be seen.

Opinions vary as to what number of bacteria constitutes adequate evidence of infection, and the variable dilution of BAL specimens adds to the uncertainty. In general, for common bacterial species such as *Staphylococcus aureus, Haemophilus influenzae,* and *Streptococcus pneumoniae,* concentrations of more than 100,000 organisms/mL of BAL fluid, in association with significant numbers of neutrophils, are adequate evidence of infection. In the absence of neutrophils (except in neutropenic patients), bacteria are more likely to represent contamination than infection. Numbers of bacteria more than 500,000 organisms/mL are common in clear-cut bacterial infection, as is the finding of intracellular bacteria. However, the interpretation is not always straightforward, especially if significant numbers of “oral flora” are also recovered. In pediatric patients, it is possible to obtain BAL specimens that are sterile, but the majority will have at least some oral flora even if there are no pathogens. In immunocompromised patients, the finding of pathogens that are not normally in the lung may be diagnostic, regardless of numbers. *P. jirovecii, Mycobacterium tuberculosis, Legionella pneumophila,* Nocardia, Histoplasma, Blastomyces, Mycoplasma, influenza virus, and respiratory syncytial virus would therefore be true pathogens; whereas Herpes simplex virus, CMV, Aspergillus, atypical mycobacteria, bacteria and Candida may not be pathogens but merely contaminants or colonizing agents.

Viruses can be grown from BAL fluid but may take weeks, limiting the utility of this assay. Using PCR to detect viruses can speed diagnosis and may be more sensitive. Another indication of viral infection is the finding of viral cytopathic effect on stains of cytospins. Fungi can be seen on stain as well as grown in culture. Distinguishing contamination or colonization from true infection can be difficult, however. Mycobacteria must be cultured on special medium and may take up to 8 weeks to grow. With significant infection, the AFB smear may be positive as well. Newer molecular methods such as nucleic acid probes or DNA amplification can speed detection.

A Gomori-Grocott (methenamine-silver) stain helps in the detection of fungi, especially for *P. jirovecii,* for which it can be diagnostic. Periodic Acid Schiff (PAS) staining is used to characterize the diffuse proteinaceous material in pulmonary alveolar proteinosis. The lamellar bodies defining the material as surfactant can be seen on electron microscopy. Prussian blue stains detect iron in macrophages from pulmonary hemorrhages or hemosiderosis. Macrophages become positive for iron staining about 50 hours after bleeding occurs, not immediately. If no further bleeding occurs, iron will clear in 12 to 14 days from the airways and in 2 to 4 weeks from the parenchyma. It can be normal to have up to 3% of macrophages staining positive for iron.

Lipid stains (Oil Red O or Sudan IV) are used to detect lipid-laden macrophages in an attemptto diagnose aspiration of food (from swallowing or gastroesophageal reflux). Although this technique is plagued by a lack of sensitivity and specificity,[33] the use of a “lipid index”[22] may increase the utility of the test. A positive lipid stain does not reveal the source of the lipid (aspiration vs. endogenous sources). Also, lipid stains may not identify children who aspirate oral secretions but who are not being fed orally.

## Research Applications of Bronchoalveolar Lavage

A widely untapped arena for BAL is its use in clinical, translational, and basic science research. In recent years, many new assays for detection of inflammatory markers, for the function of bronchoalveolar cells, and for the detection of a wide array of noncellular BAL components have been developed. Some of these are used sporadically in clinical assays, such as the determination of lymphocyte subpopulations and the identification of surfactant proteins, but most are used strictly for research purposes. One of the limitations of such assays is the lack of control data, as normal children do not ordinarily undergo flexible bronchoscopy with BAL. Development of collaborations and specimen banks may help define the normal population, allowing research to proceed more rapidly.

# Diagnostic Techniques Other Than Bronchoalveolar Lavage

## Biopsy

Mucosal samples can be obtained by direct biopsy. However, in practical terms, the only location from which a specimen can be readily obtained is from the carina; the biopsy forceps must contact the airway wall at a near-perpendicular angle. The very small forceps capable of passing through the 1.2 mm suction channel of pediatric bronchoscopes are usually inadequate for this purpose.

Endobronchial lesions (granulation tissue, tumors) can be readily biopsied under direct visual control. The forceps are advanced to the lesion, opened, pressed into the surface of the lesion, and then closed. Bleeding may result, and care must be taken to avoid biopsy of obviously vascular lesions. Topical application of a vasoconstrictor such as oxymetazoline can help control bleeding.

Biopsy of lesions adjacent to the trachea or central bronchi is possible, utilizing transbronchial needle aspiration (TBNA). The operator must be absolutely certain that the “lesion” being biopsied is not vascular; a contrasted CT scan and/or endobronchial ultrasound can be essential to safe conduct of TBNA. TBNA is a very uncommon procedure in pediatric patients, and if it is felt to be necessary, the pediatric bronchoscopist would be wise to consult with an adult interventional bronchoscopist.

TBBX is often used in adult patients in the evaluation of diffuse lung diseases or suspected malignancy. Forceps are advanced through the bronchoscope and into a peripheral site, as guided by fluoroscopy. There is a substantial risk of brisk hemorrhage, as well as pneumothorax. TBBX is rarely if ever indicated in pediatric patients, other than lung transplant recipients, in whom it is important to evaluate for rejection. The specimens are very small, and for most nontransplant pediatric patients, a thoracoscopic biopsy is more likely to yield a diagnosis.

## Bronchial Brushing

A cytology brush can be used to obtain a large number of epithelial cells from the bronchial mucosa. In pediatric patients, this is most often performed for evaluation of ciliary motility and ultrastructure. The brush is passed through the bronchoscope, the mucosa is gently abraded with the brush, and then the brush is retracted to the tip of the bronchoscope, which is then withdrawn from the airway (this is best done through an endotracheal tube or LMA). The brush is then advanced and cut, delivering the brush and specimen into a suitable container. If the brush is pulled through the suction channel of the bronchoscope, most of the specimen may be lost.

Brushes are also used to obtain specimens for microbiologic diagnosis. One potential advantage of bronchoscopy is that specimens can be obtained from the lower airways without contamination by mouth flora. Unfortunately, however, there is a significant risk of such contamination by passage of the bronchoscope through the nose or mouth on the way to the distal airways. Specimens obtained by simple aspiration through the bronchoscope often show evidence of oral flora. To surmount this problem, a protected microbiology specimen brush has been developed[34]; this brush is protected by two concentric sheaths; the outer sheath is plugged with wax to prevent secretions in the bronchoscope channel from contaminating the brush. This specimen collection system functions very well to avoid contamination of the brush specimen by secretions present in the suction channel of the bronchoscope. Unfortunately, however, it does not guarantee freedom from contamination by upper airway flora. If during the preparation for the procedure and insertion of the bronchoscope any oral secretions are aspirated into the trachea and bronchi (which is an almost universal occurrence), then the site from which the specimen is collected will be contaminated, and it makes relatively little difference what technique is used to obtain the specimen. Topical laryngeal anesthesia almost always results in contamination of the trachea and at least central bronchi to some extent with oral flora. Protected specimen brushes are not small enough to use through pediatric bronchoscopes.

## Visual Analysis

The optical properties of bronchoscopes (both rigid and flexible) are such that it is extremely difficult to gauge the size of an object in view unless there is another object of known size at precisely the same distance from the tip of the scope.[35] One can estimate *relative* size, but not *absolute* size; it is not uncommon to gain the impression that the subglottic space is normal by visual examination only to find that the patient's airway will not accept a normal size endotracheal tube.

It is often possible to visualize the movement of mucus, bubbles, or debris across the mucosal surface by mucociliary transport. Normal mucociliary transport is approximately 10 mm/min, and thus readily visible in real time. These observations should be done on the anterior tracheal wall, since there will often be a flow of oral secretions along the posterior wall. If the selected marker can be seen to move across one or more tracheal rings, then one can be confident that mucociliary transport is normal. The inability to observe movement, however, does not establish a diagnosis of ciliary dysfunction (PCD), as there are many factors that influence mucociliary transport function other than ciliary beat/ultrastructure (see Chapter 71).

# Therapeutic Bronchoscopy

Therapeutic indications for bronchoscopy in infants and children primarily involve the restoration of airway patency. While the majority of such applications will involve the use of a rigid bronchoscope, considerable therapeutic benefit can often be achieved with flexible instruments as well. Therapeutic bronchoscopy is indicated when it is the best way to achieve the desired therapeutic goals. There are many techniques loosely referred to as “interventional” techniques that are used in adults, but they are much less applicable to pediatric patients. In large part this is due to the different pathologic entities encountered in the pediatric airways, but it is also due to the small size of the pediatric airways.

The *removal of foreign bodies* is one of the more common therapeutic applications of bronchoscopy in children. It is also one of the more difficult and potentially dangerous bronchoscopic procedures in children. Only under the most unusual circumstances should foreign body removal be attempted with a flexible bronchoscope. The devices that can be passed through a flexible instrument and used for foreign body retrieval are rudimentary at best, and airway management is difficult. Small, peripherally located foreign bodies may best be reached with a flexible bronchoscope but may yet be difficult to remove. Passage of a Fogarty catheter beyond the foreign body, subsequent inflation of the catheter's balloon, and gentle retraction of the catheter may help move the foreign body to a more central location from which it may be more easily recovered. Care must be taken to avoid pushing the foreign body to a more distal position.

When the foreign body is a manufactured object and can be identified beforehand, it is helpful to practice on a duplicate object to ensure that the forceps chosen will secure a firm grasp of the object. There is a great variety of forceps available for use with different types of foreign bodies. Foreign body extraction may be complicated by the presence of inspissated secretions or granulation tissue. Foreign bodies such as nuts, which may fragment, may be present in multiple sites, and a very thorough examination of all bronchi should be made after removing any foreign body. In rare circumstances, such as a straight pin lodged in the periphery of the lung, a flexible bronchoscope may be the only suitable instrument.

*Mucus plugs or blood clots* in the airways causing atelectasis will usually yield to endoscopic treatment. Localized trauma from endotracheal suctioning is a common cause of mucus plugs. Children with small (usually organic) foreign bodies, cystic fibrosis, asthma, allergic bronchopulmonary aspergillosis, or pneumonia may also develop central mucus plugs. In some cases, the plugs must be removed with forceps, much as though they were a foreign body. Most mucus plugs, however, will yield to suctioning through a flexible bronchoscope. By touching the tip of the flexible bronchoscope to the proximal surface of the mucus plug and applying constant suction while withdrawing the instrument, plugs much larger than the diameter of the suction channel can often be removed, even if in pieces. Because mucus plugs and clots extend into distal bronchial branches, they have “roots” that often make extraction challenging and time-consuming. Local lavage with saline or a mucolytic agent (dornase alfa) can also be helpful to dislodge a mucus plug. In older patients, it may be feasible to extract large clots or mucus plugs with a cryoprobe.

*Tracheal or bronchial stenosis* can sometimes be effectively managed endoscopically, especially if the stenosis is short; longer lesions are usually best dealt with surgically. A very narrow, membranous stenosis may be dilated with the bronchoscope or a small endotracheal tube, for acute relief, and then managed more definitively by other means. In general, the most effective technique for dilation is the application of radial force through an angioplasty catheter. These devices are less than 2 mm in diameter, can be passed through the (adult) bronchoscope working channel, and then inflated to high pressure (as much as 20 atmospheres) to a defined diameter. Care must be taken in selection of the appropriate catheter (err on the side of caution), as rupture of the airway is a potential complication.

A relatively short stenosis due to dense scar tissue can also be treated by laser. While a laser is intuitively attractive, it is also potentially a very dangerous tool. Vaporization of tissue produces steam, which can cook surrounding normal tissues. Exuberant use of the laser can also lead to more scarring as the lesion heals; it is good practice to limit laser excision of a circumferential lesion to three points, leaving untreated tissue between the lased areas (as appropriate, the untreated areas can be handled at a subsequent procedure). Furthermore, if the laser beam penetrates the target tissue, there is nothing to stop it from affecting tissue distally with potentially catastrophic consequences. Therefore, great caution must be exercised in the endoscopic use of any laser such as using the lowest workable power setting, short, intermittent bursts, and careful visual control of the effect. In benign lesions, it may be preferable to merely desiccate the target tissue, rather than vaporize it, allowing the treated tissue to slough over the next few days to weeks. The use of a laser in the airways always requires a follow-up evaluation, and possibly repeated treatments. The use of a laser can also be combined with balloon dilation.

Lasers that are useful in the pediatric airways include the blue light lasers (KTP, argon) and $CO_2$. The blue light lasers offer good hemostasis and can be used through very small fibers (as small as 0.3 mm diameter), which can be inserted through the suction channel of pediatric bronchoscopes and precisely positioned. The fibers are relatively stiff, however, and the tip of the instrument cannot be deflected to a sharp angle, thus limiting the sites that can be reached with the laser. The $CO_2$ laser is generally used without a fiber, and is primarily used in the upper airway, perhaps to the mid-trachea. Other lasers are available, and their use depends on institutional factors as well as patient needs.

*Mass lesions in the airways* can often be dealt with effectively with a bronchoscope. Granulation tissue is the most common such lesion and may result from foreign bodies, mycobacterial infection, or mechanical trauma associated with artificial airways. Less commonly, tumor masses may be found in children, usually a hemangioma or a bronchial carcinoid tumor.

Benign mass lesions can be resected, if appropriate, with forceps, an endoscopic cautery electrode, or a laser. The operator must be alert to the potential for hemorrhage with vascular lesions such as hemangiomas or carcinoid tumors; biopsy (or forceps removal) of such lesions is rarely a bright idea. Malignant lesions, or lesions that extend through the bronchial wall, are usually best dealt with surgically rather than endoscopically, although endoscopic resection may be employed for temporary relief of obstruction in selected cases. In general, the use of endobronchial forceps is easier with rigid bronchoscopes; in addition, there is better potential for control of bleeding, and the forceps are larger and more readily manipulated than the small, flexible instruments that can be used with flexible bronchoscopes. Laser applications may utilize either rigid or flexible instruments. A monopolar cautery electrode as small as 3Fr can be passed through the suction channel of a pediatric bronchoscope and used to directly destroy endobronchial lesions such as granulation tissue or papillomata. Advantages of this technique include the ability to fully flex the tip of the bronchoscope, thus accessing lesions in the upper lobes, and the fact that the effect is limited to the tissue in direct contact with the tip of the electrode. However, as with a laser, care must be taken to limit collateral damage by using the lowest effective power and short, repeated applications.

There is a variety of *stents* that may be placed to ensure airway patency under certain conditions. However, none of these devices are truly appropriate for pediatric patients, and there is little experience with such devices in children, especially young infants. Great caution should be taken when considering stenting in pediatric patients. Stents are associated with numerous problems, such as mucus retention, formation of granulation tissue, and migration of the stent. In growing children, a stent will have to be replaced periodically; otherwise, the child will develop an iatrogenic stenosis. However, if the stent has become embedded in the airway mucosa, it may be extremely difficult to remove safely.[36] Nevertheless, in highly selected patients, stenting may be the only way to achieve and maintain airway patency. The US Food and Drug Administration, which approves medical devices, strongly cautions against using expandable metal stents in benign conditions (which includes almost all potential pediatric applications).[37]

*Alveolar filling disorders* such as alveolar proteinosis or lipid aspiration are treated by bronchopulmonary lavage. While this may be accomplished, after a fashion, directly through a bronchoscope, it is more effective to utilize large volumes of saline and to lavage relatively large areas of the lung at one time. In adults, a double-lumen endotracheal tube is used; this is not feasible in patients younger than approximately 10 years, as the smallest double lumen endotracheal tube is 26 Fr (the patient's larynx must accept a 6.5 mm endotracheal tube, which is approximately 8.5 mm in outer diameter). A flexible bronchoscope can be used to position a single-lumen cuffed endobronchial catheter through which an entire lung can be lavaged with large volumes, while ventilation is maintained with a nasopharyngeal tube.[28]

Flexible bronchoscopes are valuable in the management of tracheostomy and endotracheal tubes. Problems with tube positioning or tube patency can be resolved quickly with a flexible instrument.

Bronchoscopy can be useful in the management of *intractable air leaks*. A systematic search for the bronchus leading to the air leak can be made with a Fogarty catheter, which is inflated in a bronchus while observing the air leak from the chest tube (this requires that there be an active leak during the evaluation). When the site of the leak is defined, fibrin glue or Gelfoam can be packed into the bronchus leading to the site of the air leak. In older patients, a one-way valve can be placed in the bronchus leading to the leak and removed after the lung has healed.[38] More proximal leaks, as from the stump of a resected bronchus, can be treated directly by application of tissue adhesive.[39]

*Bronchoscopic intubation* is a technique that facilitates difficult or complicated intubations and should almost always be successful if the right instruments are available and the operator is skilled in their use. A flexible bronchoscope is passed through a suitable endotracheal tube. The bronchoscope is then passed into the trachea (usually through the nose, but an oral approach may be used instead). With the tip of the bronchoscope held just above the carina, the endotracheal tube is advanced over the flexible bronchoscope until its tip is seen through the bronchoscope. The bronchoscope must be held so that its shaft is straight while the endotracheal tube is advanced over it; otherwise, damage to the bronchoscope (or bronchi) may result. The bronchoscope is withdrawn, the patient is ventilated, and then the bronchoscope is again inserted to verify the position of the endotracheal tube and to ensure that the anatomy and patency of the distal airways are adequate.

A skilled bronchoscopist should be able to accomplish a bronchoscopic intubation in 30 seconds or less. When bronchoscopic intubation is required, there must be a plan to achieve safe extubation—if the patient fails extubation, a flexible bronchoscope may be urgently needed to restore a safe and effective airway.

## Complications of Bronchoscopy

Other than death of the patient, the most serious complication of a bronchoscopy is to have performed the procedure and obtained the wrong (or no) answer or the wrong (or inadequate) therapeutic result. Every procedure has potential for complications ranging from trivial to lethal. Bronchoscopy is no exception, although reported lethal complications of bronchoscopy in pediatric patients are rare. The risk of complications is a function of inherent risk factors in the patient (e.g., disease state, severity of disease, and age), the procedure performed, the skill and experience of the bronchoscopist and the bronchoscopy team, and the patient's preparation for the procedure.

In general, the risk is greater with rigid bronchoscopy than with flexible bronchoscopy. This is because foreign body extraction is perhaps the most challenging, difficult, and risky bronchoscopic procedure commonly performed in pediatric patients and is always done with a rigid instrument. In addition, the relatively large diameter and rigid nature of the rigid bronchoscope make it more likely to traumatize the mucosa of the subglottic space or airways. However, flexible bronchoscopy is not immune to serious complications, and at least one death has been reported in association with a flexible bronchoscopy in a pediatric patient.[40] Disaster lurks around the corner for the unwise or unwary.

*Mechanical complications* of bronchoscopy result from direct trauma to the airway. Pneumothorax or pneumomediastinum, mucosal edema, and hemorrhage are most common. Such complications are more likely when auxiliary instruments such as biopsy forceps are used. The greatest risk is incurred during the extraction of foreign bodies and in the performance of TBBX. The risk of mechanical complications can be reduced by careful selection of instruments and procedures. Epistaxis is common in thrombocytopenic patients; consideration should be given to passing the flexible bronchoscope via an orotracheal tube instead of transnasally. Since most such patients are also immunosuppressed, this practice will also reduce the risk of contamination of the BAL specimen (and the lower airways) with oral secretions and flora. Patients with large adenoids often develop epistaxis when a nasopharyngeal tube is passed to facilitate ventilation during the procedure; NP tubes should only be placed after examination of the nasopharyngeal airway.

When a flexible bronchoscope is passed through an endotracheal tube, there is the potential for the development of inadvertent PEEP. It is easy to force air through the tube around the bronchoscope, but exhalation is passive, and if the expiratory resistance is high, intrapulmonary pressure may increase to the point of impairing pulmonary perfusion or producing a pneumothorax.

*Physiologic complications* of bronchoscopy include hypoxia, hypercapnia, hypotension, laryngospasm, bronchospasm, cardiac arrhythmias, and aspiration. There is a constant risk of hypoventilation during bronchoscopy due to anesthesia or to airway obstruction, and smaller patients are at greater risk of airway obstruction. All bronchoscopes (rigid as well as flexible) produce some degree of airway obstruction. Vagal stimulation due to inadequate topical anesthesia or catecholamine release due to inadequate sedation/anesthesia may result in cardiac arrhythmias. Laryngospasm or bronchospasm are usually due to inadequate topical anesthesia. Seizures can result from lidocaine toxicity. The risk of physiologic complications can be reduced by careful attention to patient preparation as well as anesthetic and monitoring techniques.

*Bacteriologic complications* of bronchoscopy include the introduction of infectious agents into the lungs from the patient's own upper airway or from another patient if the instruments are not adequately cleaned and sterilized. Infection in one part of a patient's lung can be spread to other areas. Although the risk appears to be low, it is possible that bacterial endocarditis could result in susceptible patients following bronchoscopy; appropriate antibiotic prophylaxis should be considered for the patient at high risk. However, if a BAL specimen is to be obtained for culture, the prophylactic antibiotics should not be administered until after the BAL specimen is obtained. Bronchoscopy can also result in spread of infectious agents from the patient to the personnel performing the procedure, so precautions should be taken to protect personnel. Older patients known to have cavitary tuberculosis, for example, represent very high risk to the bronchoscopy team, and bronchoscopy should in most cases be delayed until appropriate therapy has been given for a sufficient time to greatly reduce this risk.

There are also *cognitive risks of bronchoscopy:* the failure to obtain useful information or making the wrong diagnosis. Even failure to perform bronchoscopy when it is the best or only way to obtain information necessary for the patient's care could be considered an error or complication. The bronchoscopist must be aware of the many pitfalls that await the unwary.[41] Video recording the procedure allows later review of the observations, and sometimes leads to a revision of the diagnosis. Serious consideration should be given to recording all procedures, to augment teaching, consultative reports, and even research data acquisition.

Cognitive risks are reduced by adequate training and experience on the part of the bronchoscopist and support staff. There is no simple guideline as to the requirements for training of a bronchoscopist; obviously, inherent aptitude varies greatly from individual to individual. The bronchoscopist must develop both manual skills and an effective knowledge of anatomy, pathology, indications for bronchoscopy, and techniques for anesthesia/sedation to safely and effectively perform procedures. A formal, comprehensive training program should be a prerequisite, but there is no substitute for good judgment and experience. Most authorities suggest that a minimum of 50 to 100 procedures performed with a suitable mentor are required before an individual should be certified to do bronchoscopy independently.[42,43]

Complications of bronchoscopy may include more than adverse effects on the patient or personnel. Failure to utilize a bite block when a flexible bronchoscope is passed through a patient's mouth, for example, can result in destruction of the instrument. Flexible bronchoscopes currently cost more than $27,000 (USD), and smaller bronchoscopes are more fragile. Flexible bronchoscopes are often damaged during passage through endotracheal tubes, and biopsy forceps can also perforate the suction channel, thus decommissioning the instrument.

## Economic Aspects of Bronchoscopy

Bronchoscopy is not a simple, inexpensive procedure. Total cost will depend on institutional factors as well as the nature and extent of the procedure performed. Specific costs include support for equipment and procedure rooms, consumable supplies, laboratory charges for processing of diagnostic specimens, monitoring of the sedated patient before and after the procedure, record keeping, support of ancillary staff, and professional fees. When general anesthesia is used instead of sedation performed by the bronchoscopist, costs are generally higher, but this should not be a significant factor in decision making if the services of an anesthesiologist significantly enhance the safety of the patient. In large part because of the need for general anesthesia, rigid bronchoscopy may be more expensive than flexible,[44] but again, the decision as to choice of technique should be made on the basis of the patient's medical needs.

Although definitive studies of cost-effectiveness in pediatric practice have not been reported, bronchoscopy is often a cost-saving procedure. For example, the early identification of a specific infectious agent in the immunocompromised patient with pneumonia can mean that more expensive, multiple antimicrobial therapies can be avoided (thus also reducing potential risk of complications of such treatment). Young patients with cystic fibrosis admitted to hospital for intensive therapy are not infrequently discovered at bronchoscopy to have no evidence of bacterial infection; evidence may be found instead for other causes of the persisting symptoms (such as gastroesophageal reflux with microaspiration). The definitive identification of causes of pulmonary symptoms such as stridor can reduce “doctor shopping” and multiple expensive diagnostic evaluations. The cost associated with missed diagnoses (when bronchoscopy is not performed) may be enormous.

“We dance around the patient, and suppose… but the bronchoscope sees into the patient, and knows” (with apologies to Robert Frost—“The secret”).

# Diagnostic Imaging of the Respiratory Tract

*Thomas Semple FRCR, MBBS, BSc, Carolyn Young HDCR, Øystein Olsen PhD, Catherine Owens BSc, MBBS, MRCP, FRCR, FRCP*

Pediatric chest radiology is a complex subject, and the clinical sections of this book cover a full understanding of all relevant pathologies with which it aids diagnosis. This chapter gives a brief overview of the imaging modalities used to help achieve an accurate and timely diagnosis, thus enabling prompt treatment of the many varied pathologic entities encountered within the pediatric thorax. The dedicated reader may wish to consult more specialized and comprehensive texts.[1–3]

The utility of imaging modalities is often uncertain because of (1) an increasing number of available techniques; and (2) the presence of numerous rare disease entities in children. Nevertheless, modern clinical practice is highly dependent on radiology.

We will discuss areas of specific concern within the pediatric age group, in particular: (1) radiation protection; (2) technical challenges (e.g., motion and breathing artifacts); (3) developing anatomy and pathophysiology (see Chapters 2 and 6); and (4) different interpretation of images compared with images obtained in adults (to a certain degree).

# Plain Radiography

The plain chest radiograph remains the basis for the evaluation of the chest in childhood. In the neonate, satisfactory images can be obtained in incubators using modern mobile x-ray apparatus. The baby lies on the cassette, and the detector is exposed. Although one can automate triggering of the exposure, an experienced radiographer will usually be able to judge the end of inspiration. An adequate inspiration occurs with the right hemidiaphragm at the level of the eighth rib posteriorly. Films in expiration frequently show varying degrees of opacification of the lung fields, with apparent enlargement of the heart. Films should be well collimated, with the baby positioned as straight as possible. Lordotic films should be avoided, especially if the size of the heart is of particular interest. Monitoring equipment should be removed to the extent that is clinically safe. Digital/computed radiography is particularly useful in intensive care, and the facility of data manipulation (e.g., edge enhancement) can improve the visualization of support apparatus, such as tubes and lines.

Children older than 5 years of age can usually cooperate sufficiently to stand for a posteroanterior film in the same way as adults. In younger children, some form of chest stand is needed in which an assistant, preferably the caregiver, can hold the child in front of a cassette while standing behind a suspended protective lead apron. With proper collimation, the dose to both child and caregiver is small, and this position allows straighter positioning of the child than a position to the side. The difference between a posteroanterior projection and an anteroposterior projection in the small child is usually negligible. A high-kilovoltage technique, with added filtration and the use of a grid, allows evaluation of the trachea and major bronchi, which is important in stridor.

# Specific Features of the Chest Radiograph in Children

## The Thymus

The normal thymus (Fig. 10.1) is a frequent cause of widening of the anterior mediastinum during the first years of life. The lateral margin often shows an undulation, the thymic wave, which corresponds to the indentations of the ribs on the inner surface of the thoracic cage. Particularly on the right, the thymus may have a triangular, sail-like configuration. The thymus may involute in times of stress, and steroids can induce a decrease in size. At times, the differentiation of a physiologic thymus from pathology in the anterior mediastinum can be difficult. Ultrasound examination will usually differentiate cystic lesions from the homogeneous normal thymic tissue (see ultrasound section later in this chapter). Occasionally, the normal thymus can act as a significant space-occupying structure in the superior mediastinum, and in such cases, differentiation may be helped by either ultrasound or magnetic resonance imaging (MRI), which shows a homogeneous echogenicity/signal within a normal thymus. On MRI, a normal thymus has an intermediate signal on T2-weighted images (similar to the spleen and lymph nodes) and shows minimal uniform enhancement on T1-weighted images after intravenous contrast medium injection (Fig. 10.2).

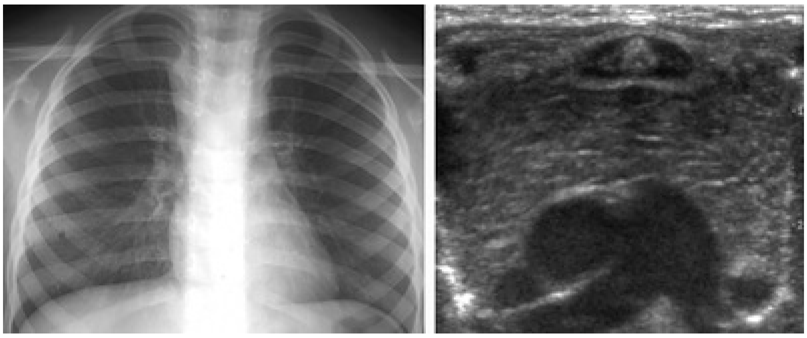

**FIG. 10.1** Chest radiograph demonstrating slight widening of the superior mediastinum. Corresponding ultrasound demonstrates normal thymic tissue. (Image courtesy of P Tomà.)

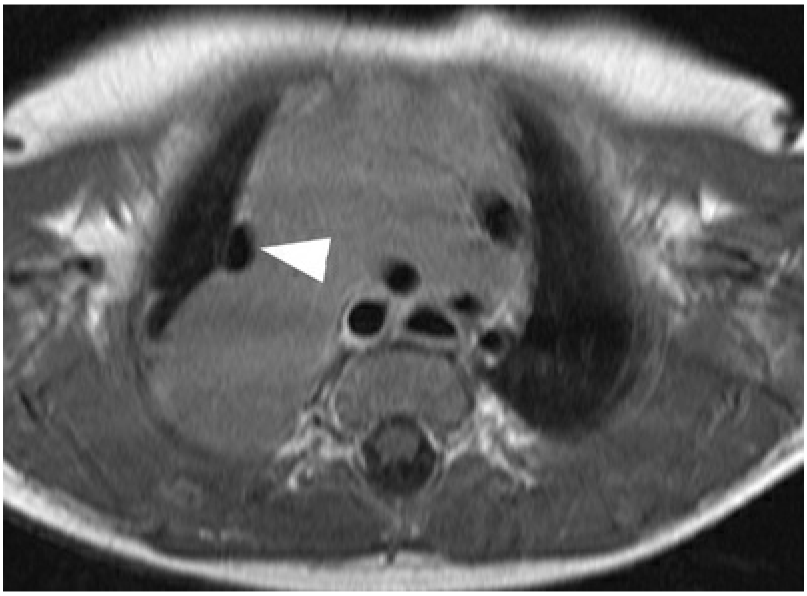

**FIG. 10.2** Chest radiograph *(not shown)* in a 3-month-old child showed an unusual upper mediastinal contour. Magnetic resonance imaging (T1-weighted spin echo after intravenous injection of gadolinium chelate) shows a normal signal and no abnormal contrast enhancement from a normal but large thymus, extending posterior to the right brachiocephalic vein *(arrowhead).* There is no sign of vascular or airway compression.

## The Cardiothoracic Ratio

In toddlers, the cardiothoracic ratio can at times exceed 0.5, and care should be exercised in overdiagnosis of cardiomegaly, particularly if the film may be expiratory.

## Kink of the Trachea to the Right

Kinking of the trachea to the right is a frequent feature of a chest film taken at less than full inspiration. This is a physiologic buckling and does not suggest a mass lesion.

## Soft Tissue

Soft tissue may be prominent in children, and the anterior axillary fold that crosses the chest wall can mimic pneumothorax. Similarly, skin folds can cast confusing shadows at times. Braids (plaits) of hair over the upper chest can mimic pulmonary infiltrations in the upper lobes.

## Pleural Fluid

Whereas in adults an early sign of pleural effusion is blunting of the costophrenic angles, in children it is more common to see lateral separation of the lung from the chest wall, with reasonable preservation of the clarity of the costophrenic angles and accentuation of the interlobar fissures. In the supine position, an apical rim of soft tissue density is seen, and if a moderate to large unilateral effusion is present, the affected hemithorax has a diffuse increase in density, with preservation of vascular markings simulating ground-glass parenchymal opacification. This is due to pleural fluid collecting in the dorsal (dependent) pleural space.

# Systematic Review of the Chest Radiograph

Without a systematic analytical approach to the pediatric chest radiograph, the possibility of missing relevant radiologic information is high. To combat this, knowledge of the various pitfalls in interpretation, anatomic variants, and pathologic processes relevant to the specific age group are vital. This is particularly important when there is one very conspicuous abnormal imaging finding, which can result in the cessation of more intense scrutiny of the remainder of the film. Therefore, an image review should follow a strict systematic order, including checking the putative identity of the radiograph, and should include the following.

## General Degree of Lung Inflation

Flattening of the diaphragm or diaphragmatic domes below the level of the eighth posterior ribs, elongation of the mediastinum, and widening of the intercostal spaces are all signs of pulmonary overinflation. Intercostal bulging of the pleura or lung parenchyma may be a sign of excessive ventilator pressures in an intubated child.

Generalized pulmonary underinflation is usually due to radiographic exposure during expiration, but it may be a real finding confirming small lung volumes (as in cases of respiratory distress syndrome [RDS] of the newborn, in which the lung parenchyma is noncompliant, or in bilateral pulmonary hypoplasia) or associated with lobar collapse.

One should also consider elevation of the diaphragm, with consequential lung compression due to bowel distention, pneumoperitoneum, or the presence of a large abdominal mass. Hence, the periphery of the radiograph (e.g., the area under the diaphragm) should always be carefully and routinely inspected as part of a systematic review.

## Asymmetrical Lung Volume

In the absence of a pneumothorax, mediastinal shift toward a lung with uniformly increased density compared with the contralateral lung is a sign of differential inflation of the two lungs. This may be caused by overinflation of the more lucent lung (e.g., due to a ball-valve mechanism in the central airways), in which case the ipsilateral hemidiaphragm would be flattened (Fig. 10.3).

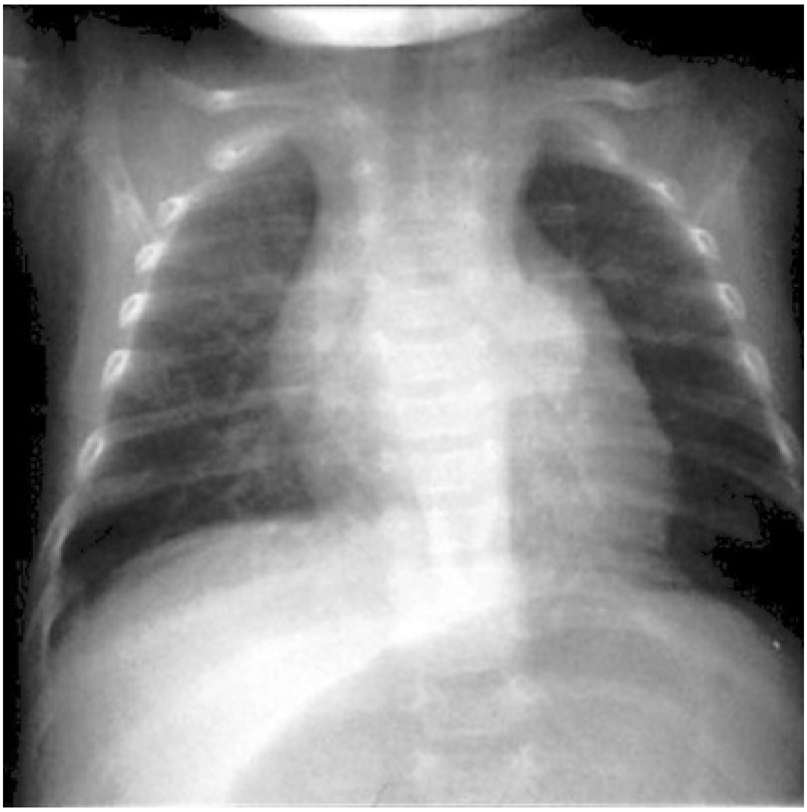

**FIG. 10.3** Chest radiograph in a young child shows a semicircular left convex distortion of the left mediastinal outline due to a bronchogenic cyst and secondary overinflation of the left lower lobe.

Alternatively, it may be caused by volume loss in the denser lung, in which case the diaphragm of the denser hemithorax would be elevated. This may be a sign of unilateral pulmonary hypoplasia, aplasia, or agenesis (Figs. 10.4–10.6), in which case the mediastinum is shifted toward the hemithorax containing the small lung, and ipsilateral elevation of the hemidiaphragm is seen. Combined overinflation of one lung and volume loss of the other can sometimes be seen secondary to mass lesions that affect the central airways (Fig. 10.7).

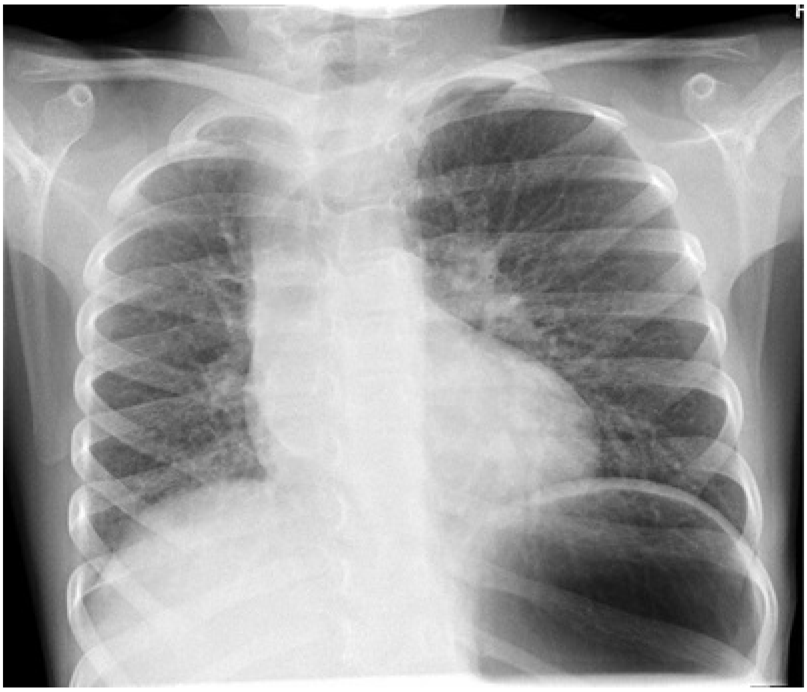

**FIG. 10.4** In a 10-year-old girl who presented with shortness of breath, this chest radiograph shows a small right hemithorax (rib crowding, diaphragmatic elevation, compensatory large left lung), but no lung opacification. This was later diagnosed as an interrupted right pulmonary artery (see Figs. 10.45 and 10.70).

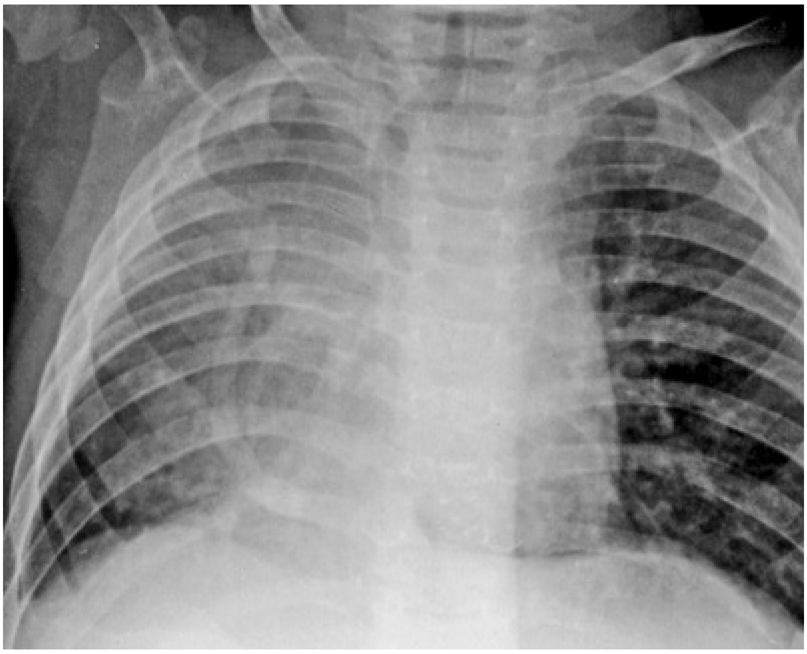

**FIG. 10.5** Chest radiograph shows a hypoplastic right

lung with an abnormal vascular structure running toward the diaphragmatic level medially. This represents systemic venous drainage of the right lung. The shape of the abnormal vein resembles a Turkish scimitar (bowed sword); hence, the denotation scimitar syndrome (see Figs. 10.44 and 10.46).

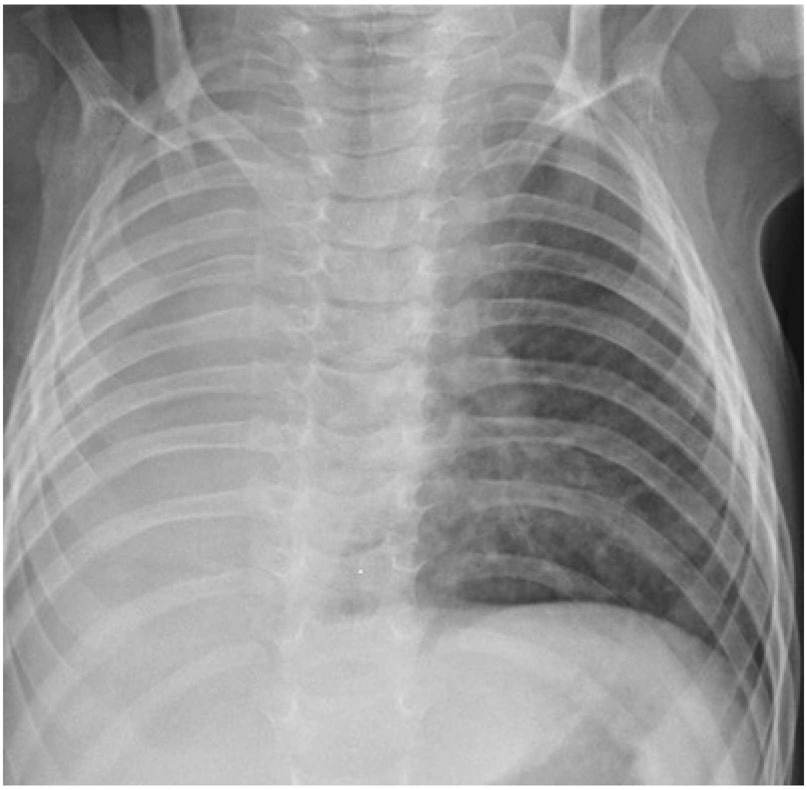

**FIG. 10.6** The right hemithorax is opacified by the mediastinal structures that are shifted to the right. However, there is no overexpansion of the left lung or pleura. On computed tomography, the right lung was absent (see Fig. 10.47).

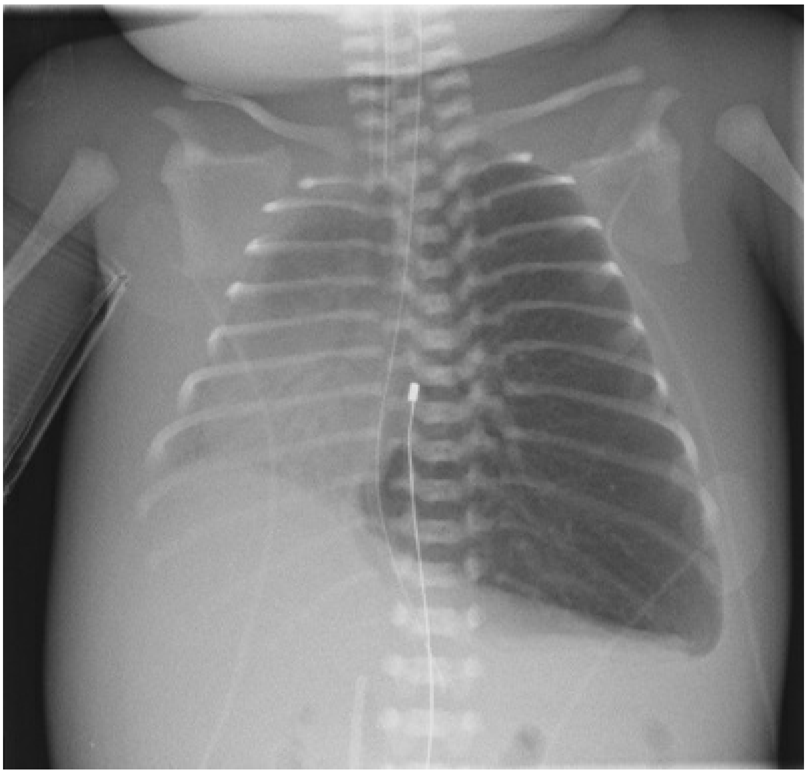

**FIG. 10.7** Chest radiograph of a neonate with respiratory distress syndrome shows an overexpanded left lung (inverted left hemidiaphragm, intercostal bulging of the left lung) as well as a small right hemithorax (elevated right hemidiaphragm, crowding of the right ribs). Both were secondary to a central bronchogenic cyst (see Fig. 10.43), although this is not apparent on the chest x-ray, but is seen subsequently on computed tomography scan.

Other causes of asymmetrical lung volumes include diaphragmatic paresis/paralysis and a large abdominal mass lesion that causes elevation of the ipsilateral hemidiaphragm. The diaphragm may also be apparently elevated secondary to a subpulmonic fluid collection. In congenital diaphragmatic hernia, the multicystic appearance of bowel contents may or may not be obvious within the thorax (Fig. 10.8). If seen, it may sometimes be difficult to distinguish from congenital cystic adenomatoid malformation (Table 10.1).

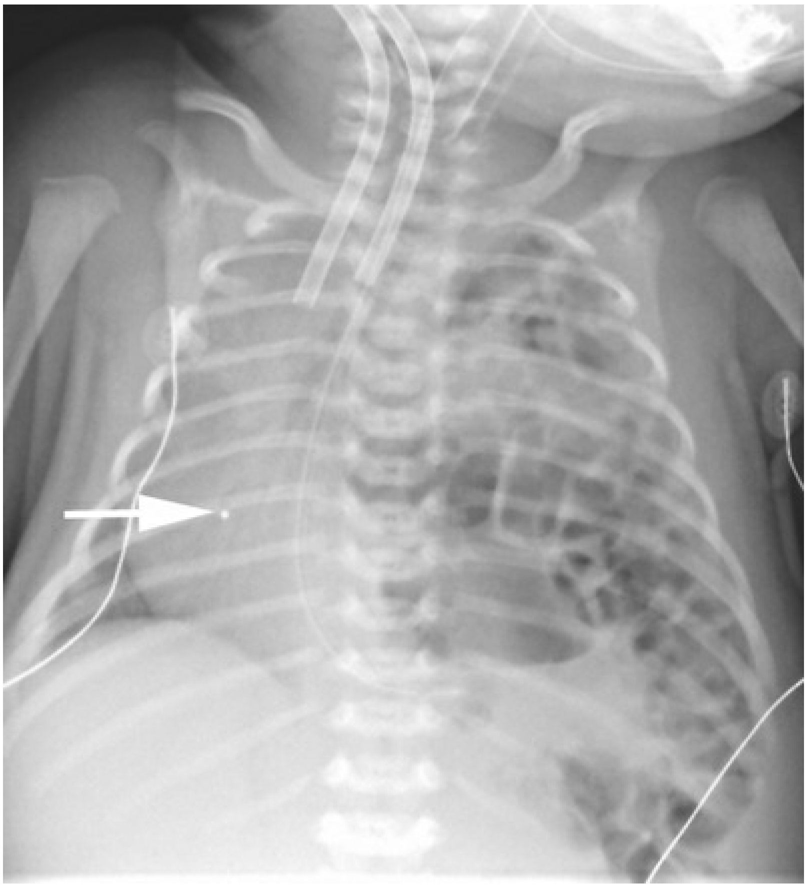

**FIG. 10.8** An infant with antenatally diagnosed left congenital diaphragmatic hernia. Chest radiograph shows disruption of the lateral left diaphragmatic outline, bowel in the left hemithorax, and mediastinal shift to the right. Note venous-arterial extracorporeal membrane oxygenation with a metal marker on the tip of the venous cannula *(arrow).* The endotracheal tube is too high.

### Table 10.1

### Differential Diagnoses in Asymmetrical Lung Volume

| | Increased Ipsilateral Density | Decreased Ipsilateral Density | Normal Density |
|---|---|---|---|
| Small lung | Atelectasis | Swyer-James syndrome (Macleod syndrome) | Hypoplasia |
| | Central airway obstruction | | Interrupted pulmonary artery |
| | Congenital venolobar syndrome | | |
| | Diaphragmatic elevation/paresis | | |
| Large | | Primary/secondary congenital | |

|  |  |  |  |
|---|---|---|---|
| lung |  | overinflation |  |
|  |  | Central airway obstruction with ball-valve effect |  |

## Lobar Overinflation

Lobar overinflation may have a similar appearance to whole-lung overinflation. However, there is usually evidence of lobar confinement because one can identify the lobar outline as it herniates across the midline, and the remaining ipsilateral pulmonary lobes show compressive atelectasis or collapse (Fig. 10.9). The left-upper, right-middle, or left-lower lobe is usually affected by congenital lobar overinflation (congenital lobar emphysema). A lateral radiograph may be helpful in deciding which lobe is involved, although computed tomography (CT) of the chest is required in most cases to clarify the anatomy and to identify a potential underlying causative abnormality. This could be an extrinsic lesion causing partial bronchial compression (e.g., a mediastinal bronchogenic cyst) or a mass within the bronchial lumen causing a ball-valve effect (e.g., endobronchial granuloma or adenoma).

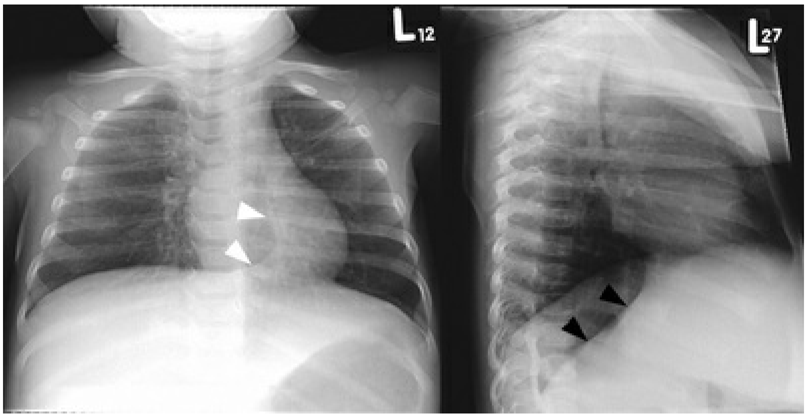

**FIG. 10.9** The lateral view is not part of a routine chest radiograph. In this case, the anteroposterior view shows probable lobar overexpansion of the right lung *(white arrowheads),* but it is not clear which lobe is involved. The lateral view is helpful, showing depression of the posterior diaphragm *(black arrowheads)* and thereby clarifying right lower lobe involvement, which is uncommon in lobar overinflation

(congenital lobar emphysema).

## Mediastinal Distortion

Mediastinal distortion may occur secondary to a mediastinal mass. Therefore, the normal outline of the mediastinum should always be reviewed. On the left, this normally constitutes the thymus, aortic arch, pulmonary outflow tract, pulmonary hilum, and left heart border; on the right, it constitutes the thymus, azygos vein, hilum, and the right heart border. In young children, the outline of the superior structures may be obscured by a normal thymus (discussed earlier), but this should never obscure the posterior paraspinal lines as the thymus lies in the anterior mediastinum. Distortion of the airways (e.g., narrowing, deviation, or splaying of the main bronchi) suggests extrinsic mass effect or functional/structural abnormalities of the airways (Fig. 10.10).

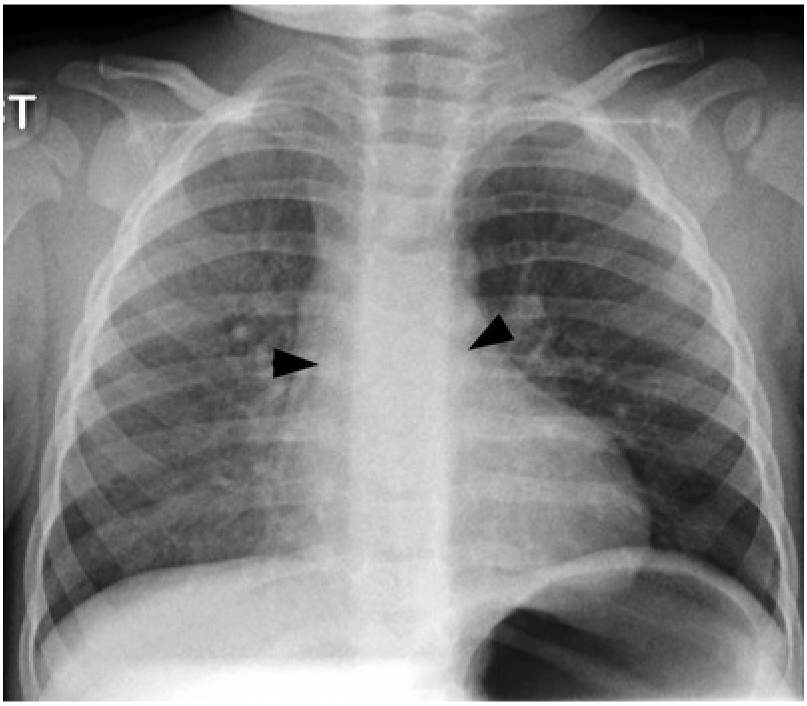

**FIG. 10.10** A 2-year-old boy presents with pyrexia. Chest radiograph shows displacement of the left main and lower lobe bronchi by a subcarinal mass *(between arrowheads)* and associated increased transradiency of the left lung due to air trapping. The mass was later proven to be lymphadenopathy caused by

*Mycobacterium avium-intracellulare.*

Mass lesions disrupting the paraspinal lines or involving the apices of the chest are most likely localized in the posterior mediastinum, and the list of differential diagnostic possibilities includes congenital abnormalities (lateral meningocele, neurenteric cyst, duplication cyst), neoplasm (neurogenic tumor), and infection (spondylodiscitis). Rib or vertebral body erosion suggests an aggressive lesion, such as infection or malignancy (e.g., neuroblastoma).

Any abnormal appearance of the thymus (discussed earlier), such as inappropriate size or shape or evidence of associated airway compression, suggests an anterior mediastinal mass lesion. Diagnostic differentials include rebound thymic hyperplasia, germ cell tumor, T cell lymphoma, and thymoma.

Any other mass lesion in the mediastinum usually originates from the middle mediastinum. In the young child, the diagnosis is likely to be a congenital abnormality (e.g., bronchogenic cyst). In the older child, the diagnosis is likely to be enlarged lymph nodes, which may be reactive or due to malignant disease (lymphoproliferative disease, which is rarely metastatic); sarcoidosis (rare, usually paratracheal); or idiopathic hyperplasia.

Lung atelectasis (discussed earlier) should be considered when there is loss of the upper mediastinal outline, even without apparent lung opacification.

## Hilar Expansion

Unlike in adults, where bronchogenic carcinoma is a common cause of hilar adenopathy, in children, hilar enlargement is often secondary to acute infection. However, prominent hila may also be seen due to enlargement of the pulmonary arteries and, in infants, due to a bronchogenic cyst (see Fig. 10.3). Distinguishing vascular from nodal enlargement can be difficult, but pulmonary arterial enlargement should result in a concave lateral hilar outline, whereas soft tissue masses are said to cause a convex lateral hilar margin, with a noticeable increase in soft tissue density at the enlarged hilum.

False impressions of hilar enlargement occur when the child is rotated on the film cassette: a hilum that is pointing away from the detector becomes more distinct from the heart shadow and consequently appears more prominent. A repeat exposure may be necessary in difficult inconclusive cases, and CT/MRI may be performed if there is doubt.

Peribronchial markings should not be prominent in children, unlike in adults. More distinct markings in the perihilar regions, particularly with coexisting general overinflation, often represent bronchial inflammation (e.g., asthma or infection). Other conditions included in the differential diagnosis will be discussed in the section on high-resolution computed tomography (HRCT). Patchy perihilar opacification, with air bronchograms, is usually due to radiographic summation of peribronchial thickening, but may be difficult to distinguish from airspace opacification (consolidation).

## Lung Opacities

The plain radiograph usually allows distinction between *atelectasis,* which is defined as parenchymal opacification with loss of volume, and *consolidation,* which is opacification without volume loss and with the outline of gas-filled bronchi (air bronchograms) (Fig. 10.11). Opacities in the lungs can be localized according to the neighboring structure, which is obscured (silhouette sign). Loss of the upper mediastinal outline is consequent on upper lobe opacification; loss of the heart borders is caused by right middle lobe or lingular opacification; and loss of diaphragmatic definition is caused by lower lobe pathology.

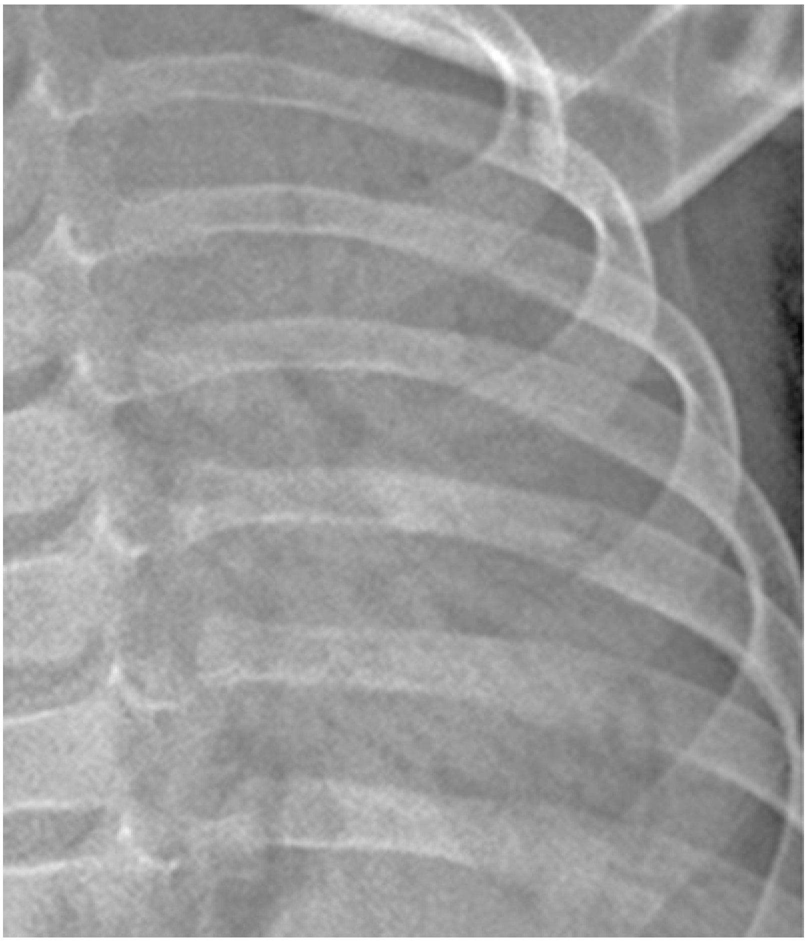

**FIG. 10.11** Consolidation. The lung parenchyma is opacified with obvious air bronchograms, but there are no vascular markings.

There are several important signs of volume loss. First, the entire hemithorax may appear shrunken, with ipsilateral mediastinal shift, diaphragmatic elevation, and crowding of the ribs. Second, adjacent noncollapsed lung may show compensatory overinflation and appear hyperlucent due to dilution of vascular shadows. Third, the hilum may be displaced, either cranially or caudally, toward the atelectasis (Fig. 10.12).

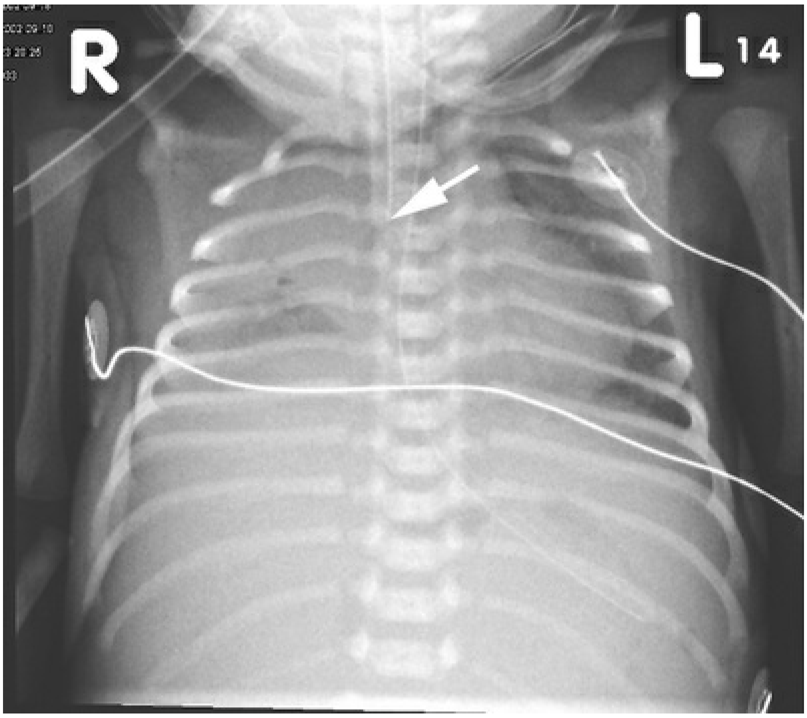

**FIG. 10.12** The tip of the endotracheal tube is in the proximal right main stem bronchus *(arrow).* There is associated atelectasis of the right upper lobe (loss of definition of the right upper mediastinal border, opacification of the right upper hemithorax, elevation of the right hemidiaphragm, and crowding of the right ribs).

It is important to recognize these signs, even with no apparent lung opacity, particularly in upper lobe atelectasis, where the affected segments, or the whole lobe, may be collapsed against the mediastinum and therefore difficult to identify.

The clinical and radiographic history of atelectasis may give important clues as to the causative pathology. Acute atelectasis may be caused by a dislodged endotracheal tube, an aspirated foreign body, or mucous plugging (Fig. 10.13) and may therefore require further nonradiologic investigation and intervention. Chronic atelectasis is more likely caused by extrinsic airway obstruction (e.g., bronchogenic cyst, mediastinal lymphadenopathy, neoplasms) or chronic infection (e.g., tuberculosis) and may therefore warrant CT/MRI. In a febrile infant with respiratory distress and multifocal segmental atelectasis that changes location over the course of hours, one may suspect infection with respiratory syncytial virus, causing bronchiolitis.

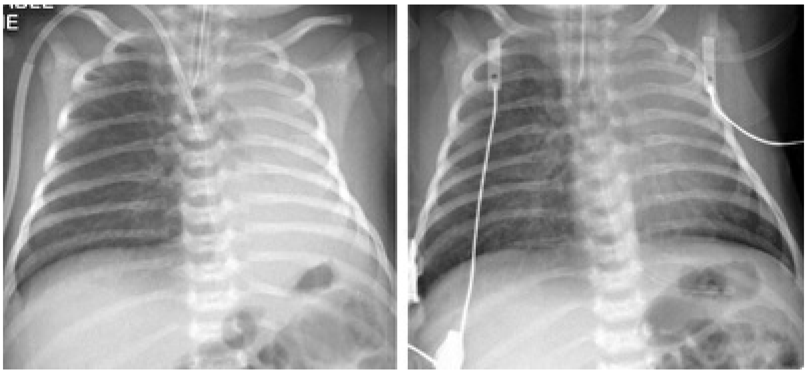

**FIG. 10.13** A neonate in the intensive care unit with increasing oxygen requirement. The chest radiograph *(left)* shows loss of the left cardiomediastinal and diaphragmatic outlines, opacification of the left hemithorax without air bronchograms, and mediastinal shift to the left. These findings strongly suggest left lung collapse, and, at bronchoscopy, a mucous plug was removed from the left main stem bronchus. Immediately afterward *(right)*, there is considerably improved aeration of the left lower lobe (diaphragm now seen), but persistent collapse of the left upper lobe (persisting mediastinal blurring and shift).

Consolidation has many causes, as in adults, and is due to any process that replaces air in the terminal airspaces with fluid, mucus, or cellular material. The clinical history, the distribution of abnormality, and the presence of associated calcification, lymphadenopathy, or pleural effusion may assist in deduction of the specific cause (Figs. 10.14 and 10.15). Typically, pulmonary edema causes bilateral patchy consolidation in a perihilar distribution as well as pleural fluid (discussed earlier), although there may be lateral predominance.

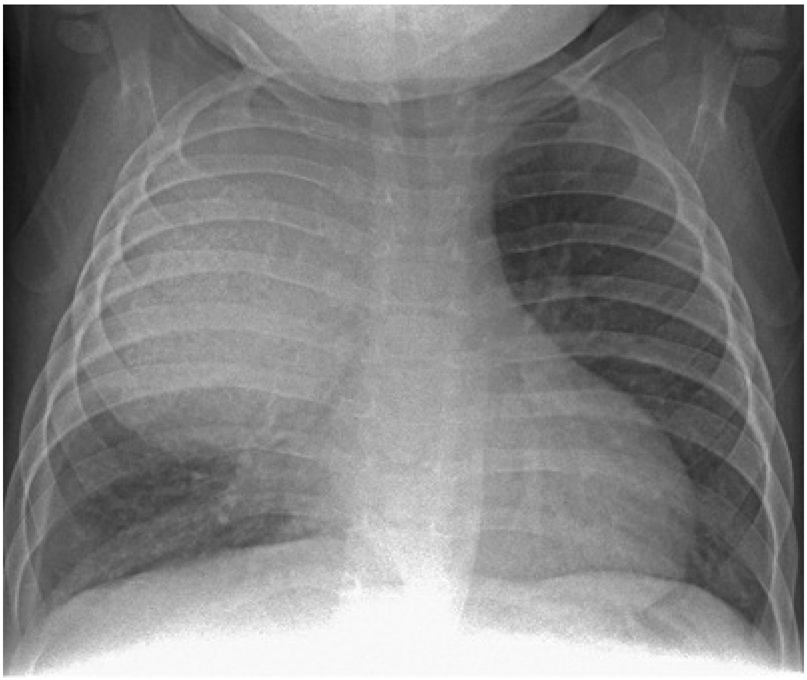

**FIG. 10.14** In a 1-year-old girl with a cough, the chest radiograph shows a calcified mass in the right upper and mid zones. Also seen is pleural fluid, which was caused by infection with *Mycobacterium tuberculosis.*

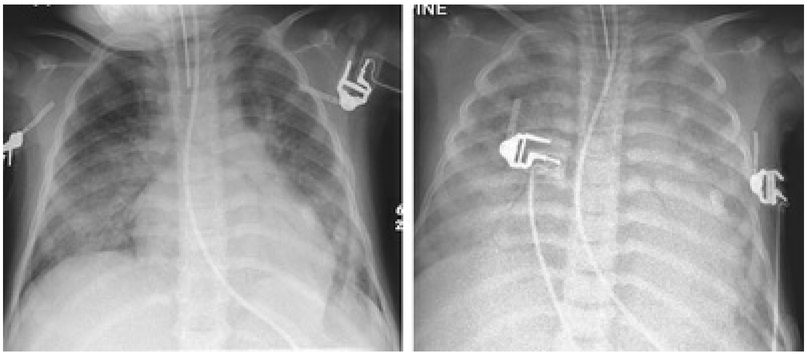

**FIG. 10.15** A 3-year-old boy who was treated in the intensive care unit after a traffic accident had increasing difficulty with oxygenation. A chest radiograph on admission *(left)* shows patchy areas of consolidation. Hemorrhagic fluids returned via the endotracheal tube. The second day *(right),* there was almost complete whiteout of both lungs, with air bronchograms and loss of the cardiomediastinal and diaphragmatic outlines. The findings confirm extensive pulmonary hemorrhage.

Ground-glass change, a description initially confined to HRCT, is also used now to describe radiographic lung opacification with partial preservation of vascular markings, with or without air bronchograms (Fig. 10.16). This sign is nonspecific and may be caused by interstitial or partial airspace opacification processes. In the neonatal setting, it is often used in the description of RDS (Fig. 10.17), and is usually combined with generally decreased lung volumes. Pleural fluid may give a similar appearance (discussed earlier). Where there is continued clinical doubt, an ultrasound can prove useful in differentiating pleural fluid from peripheral consolidation, demonstrating the presence of ultrasonographic air-bronchograms and normal arborization of pulmonary vessels in consolidated lung tissue as opposed to pleural collections (see ultrasound section later in this chapter).

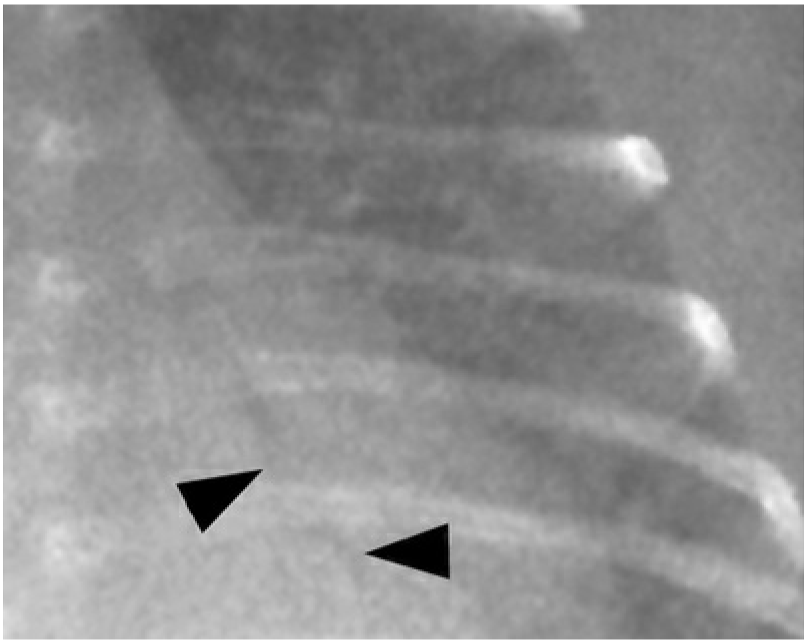

**FIG. 10.16** Ground-glass change. There is moderately increased opacity of the lung with air bronchograms *(arrowheads)*, but preservation of vascular markings.

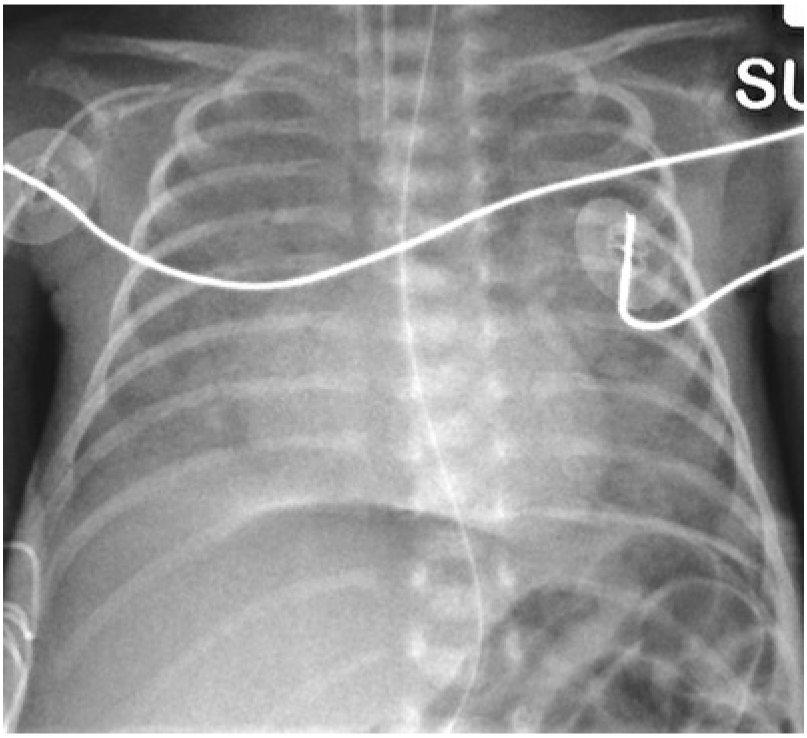

**FIG. 10.17** In a 3-week-old infant born at 32 weeks' gestation, on ventilator support, there is bilateral diffuse ground-glass change (opacification, blurring of the cardiomediastinal and diaphragmatic outlines, preserved vascular markings), in keeping with respiratory distress syndrome. Note the lucency overlying the liver, outlining the right hemidiaphragm as well as the bowel wall in the upper left quadrant. This is diagnostic of pneumoperitoneum. The child had bowel perforation secondary to necrotizing enterocolitis.

## Focal and Multifocal Lung Densities

Focal and multifocal lung densities often require additional CT/MRI for their definitive underlying cause to be elucidated, except in cases with clear clinical evidence of infectious pneumonia. In children, pneumonic consolidation often has a more distinct, rounded appearance (round pneumonia), which should be recognized and followed with plain radiographs only. In equivocal cases, CT/MRI is necessary for further characterization of the lesion. Differential diagnosis of a solitary parenchymal lesion includes congenital malformation, such as sequestration (usually in the posterobasal left lower lobe), microcystic congenital cystic adenomatoid malformation, and vascular malformation. A lung abscess may have no apparent gas-fluid level.

Multifocal lesions may represent infectious processes (e.g., fungus, tuberculosis, papillomatosis, or septic emboli) (Fig. 10.18), granulomatous disease, Langerhans cell histiocytosis, other inflammatory disease (Figs. 10.19 and 10.20), diffuse interstitial lung disease (Fig. 10.21), or metastases (e.g., nephroblastoma, hepatoblastoma, malignant germ cell tumor, sarcoma).

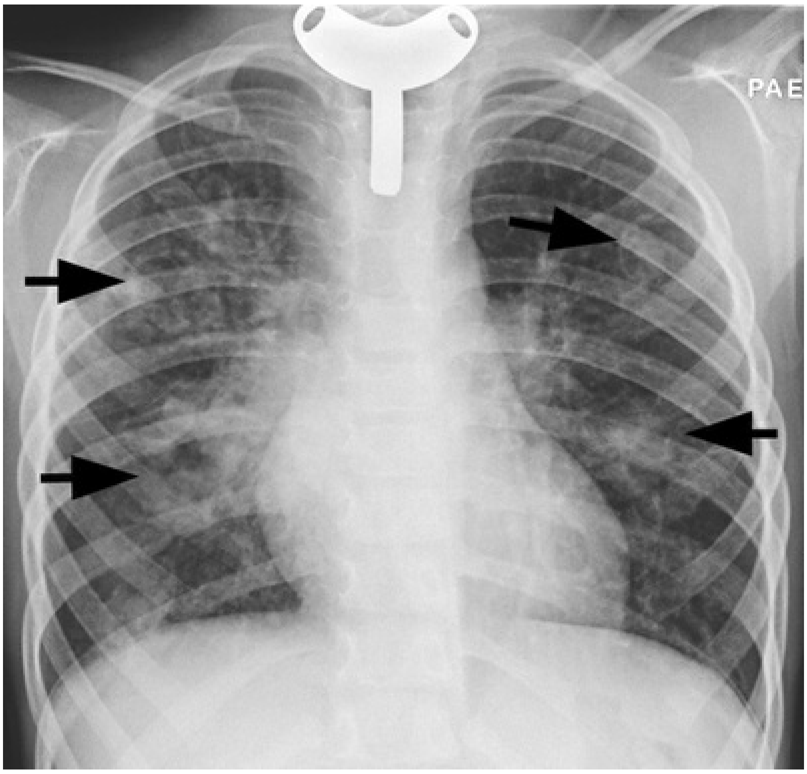

**FIG. 10.18** In a 13-year-old boy with a tracheostomy tube because of laryngeal papillomatosis, the chest radiograph shows multiple nodular processes, some of which are cavitating, caused by parenchymal dissemination of the papillomatosis (*arrows;* see Fig. 10.48).

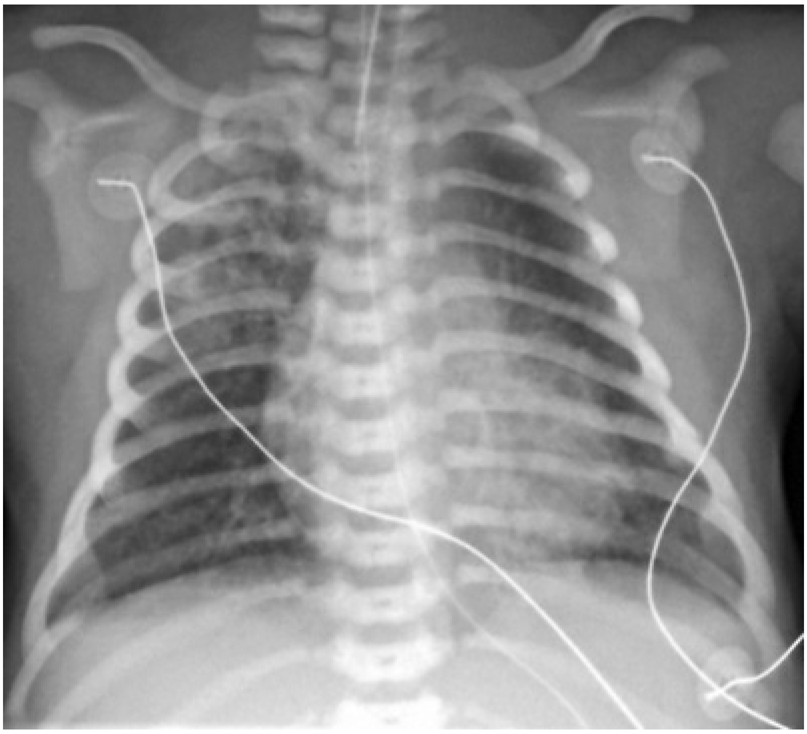

**FIG. 10.19** Radiograph of a male neonate shows patchy consolidation in the right upper zone and behind the heart on the left, with overinflated lungs. This picture is commonly seen in meconium aspiration.

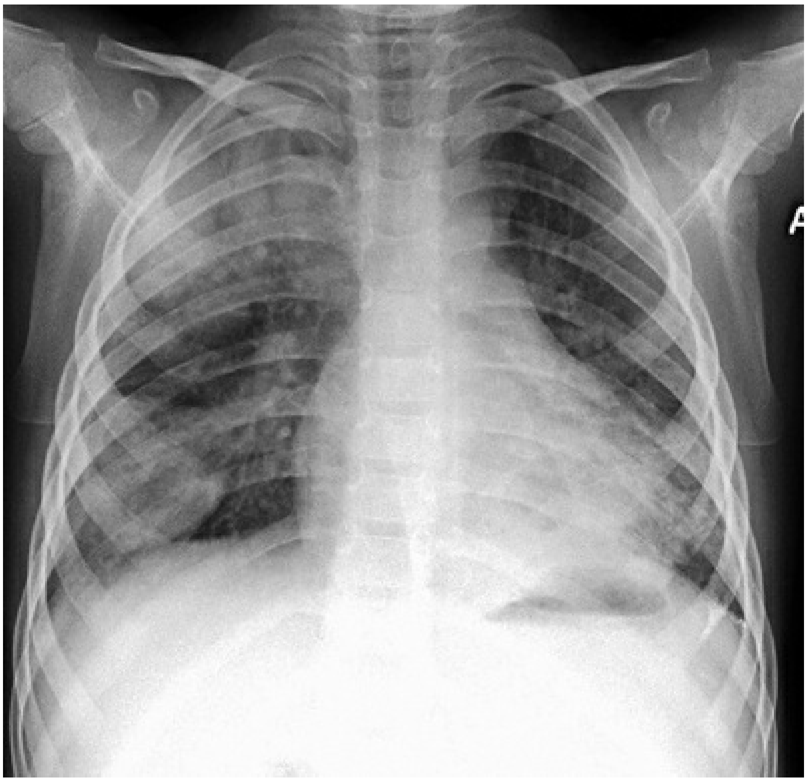

**FIG. 10.20** A 6-year-old boy presented with difficulty breathing. Inflammatory markers were increased. The chest radiograph shows areas of opacification in the right upper and mid zones, and the left mid zone, which represent vasculitic lesions (see Fig. 10.60). On plain film, this is indistinguishable from multifocal pneumonia.

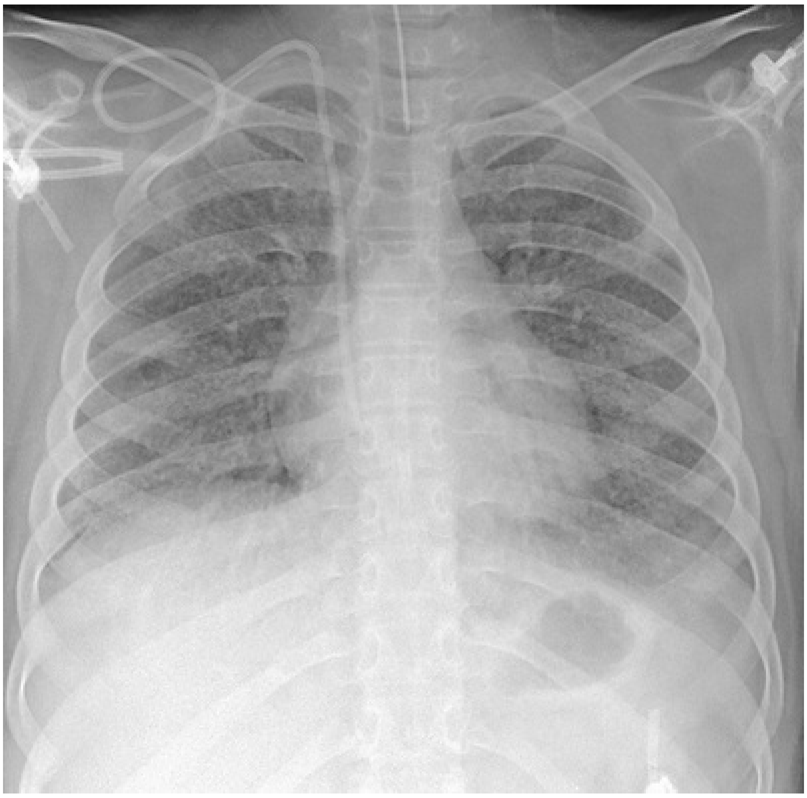

**FIG. 10.21** A 4-year-old boy undergoing chemotherapy had acute respiratory failure. Chest radiograph shows globally increased density of both lungs in a granular pattern, with preservation of vascular markings. This was due to diffuse interstitial pneumonitis caused by bleomycin (see Fig. 10.52).

Some lung lesions tend to be predominantly cystic in radiographic terms (containing a gas-filled cavity). Pneumatoceles usually follow pneumonia, which is classically caused by infection with *Staphylococcus aureus,* and occasionally by *Klebsiella.*

Multifocal, multicystic parenchymal lesions may be congenital cystic adenomatoid malformation, Langerhans cell histiocytosis nodules at the cavitating stage, granulomatosis with polyangiitis, disseminated laryngeal papillomatosis (see Fig. 10.18), or necrotizing vasculitis (see Fig. 10.20).

## Pulmonary Interstitial Emphysema

Pulmonary interstitial emphysema is a complication that occurs when high ventilator pressures are used to ventilate stiff lungs. It appears as lacelike lucencies in a linear pattern radiating from the pulmonary hilum to the surface of the lung, and it may be further complicated by pneumothorax or pneumomediastinum (Fig. 10.22–10.24). In some cases, this may be difficult to distinguish radiologically from ventilator-induced central bronchial dilation. There are rare reported cases of apparent spontaneous pulmonary interstitial emphysema in term babies who have never been ventilated. The differential diagnosis includes congenital or acquired cystic lung disease.

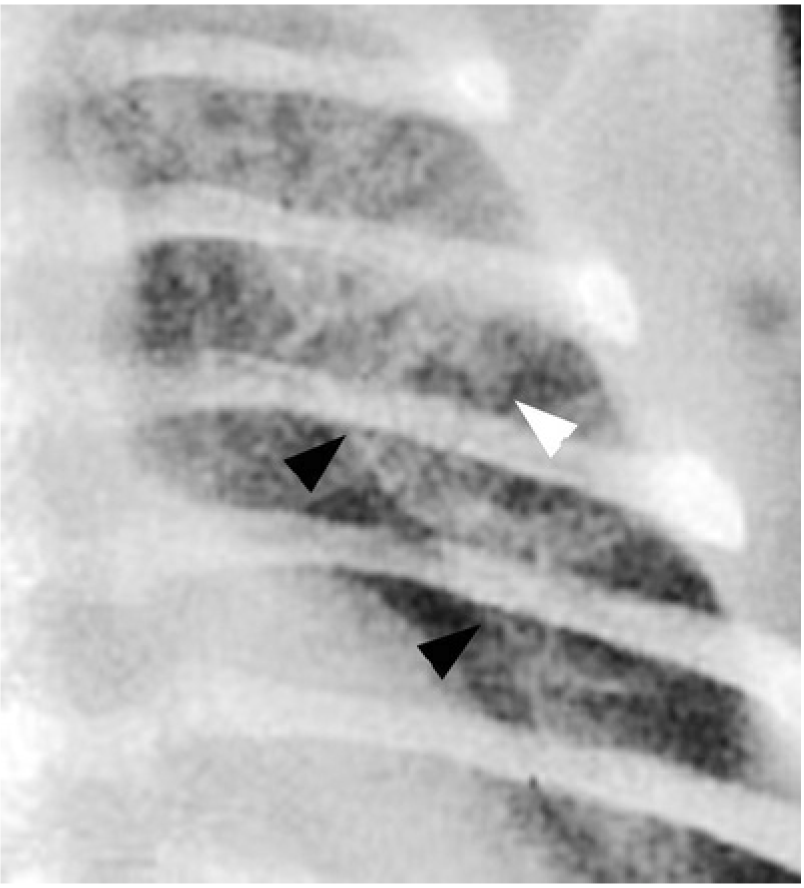

**FIG. 10.22** Detail from a chest radiograph in an infant

after long-standing ventilatory support shows monotonous tubular lucencies *(white arrowhead)* suggestive of pulmonary interstitial emphysema. The mediastinal border is seen very crisply, with a medial lung edge *(black arrowheads)* due to anterior pneumothorax.

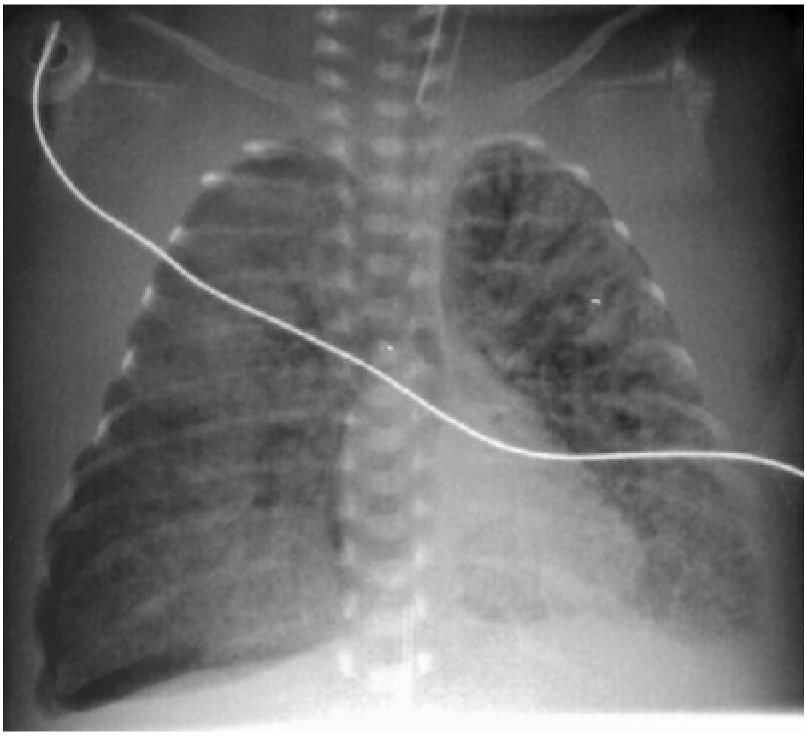

**FIG. 10.23** A 6-week-old girl born at 30 weeks' gestation was very difficult to ventilate. Chest radiograph shows overexpanded lungs that are seen bulging out intercostally, with the diaphragm flattened. Concurrently, there is increased opacification of the lungs, which is presumed to be due to respiratory distress syndrome. Linearly arranged bubbly lucencies can be seen radiating from the hila, suggesting pulmonary interstitial emphysema secondary to high-pressure ventilation. There is also a pneumothorax seen at the base of the right lung.

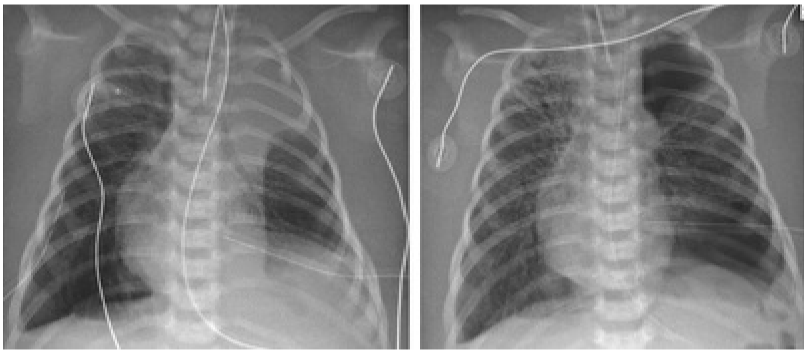

**FIG. 10.24** A 6-week-old girl was ventilated with high-pressure settings (chest radiographs show a flattened diaphragm and splayed ribs). After an acute exacerbation *(left),* the radiograph showed collapse of the left upper lobe (opacification without air bronchograms, increased interlobar fissure, and elevated diaphragm). The next day *(right),* the left upper lobe had reexpanded, but a left pneumothorax is seen. Linear bubbly lucencies can be seen from the hila to the lung edges, suggesting pulmonary interstitial emphysema.

## Lung Abscess

A lung abscess is a cavitated lesion that normally contains both fluid and gas. The consequent gas-fluid level is easily recognized, but it may be missed if the x-ray beam is not tangential (i.e., horizontal) to the gas-fluid interface. With a diverging beam, the fluid level appears more blurred and meniscoid (Fig. 10.25).

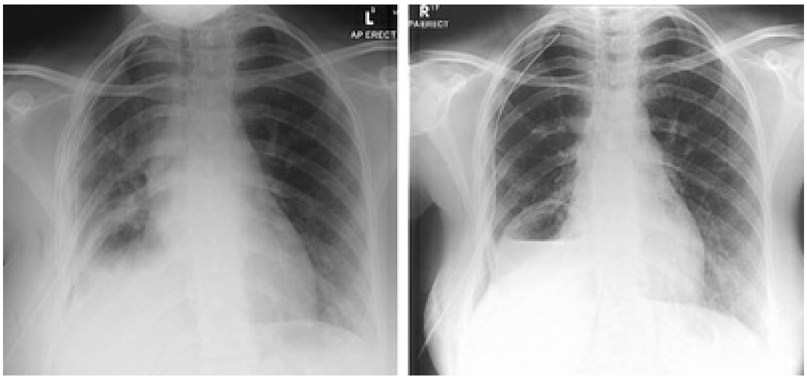

**FIG. 10.25** Two chest radiographs obtained in the same patient on the same day. The right is a true erect exposure showing the gas-fluid level of an abscess

within the right lung, whereas the left is semierect and does not show the gas-fluid level of the abscess.

## Diffuse Interstitial Lung Disease

We will discuss diffuse interstitial lung disease in more detail later in the chapter in the section on HRCT. More advanced interstitial processes may be appreciated radiographically as peribronchial thickening, ground-glass change, septal lines, or interstitial nodules (Fig. 10.26; see also Fig. 10.21).

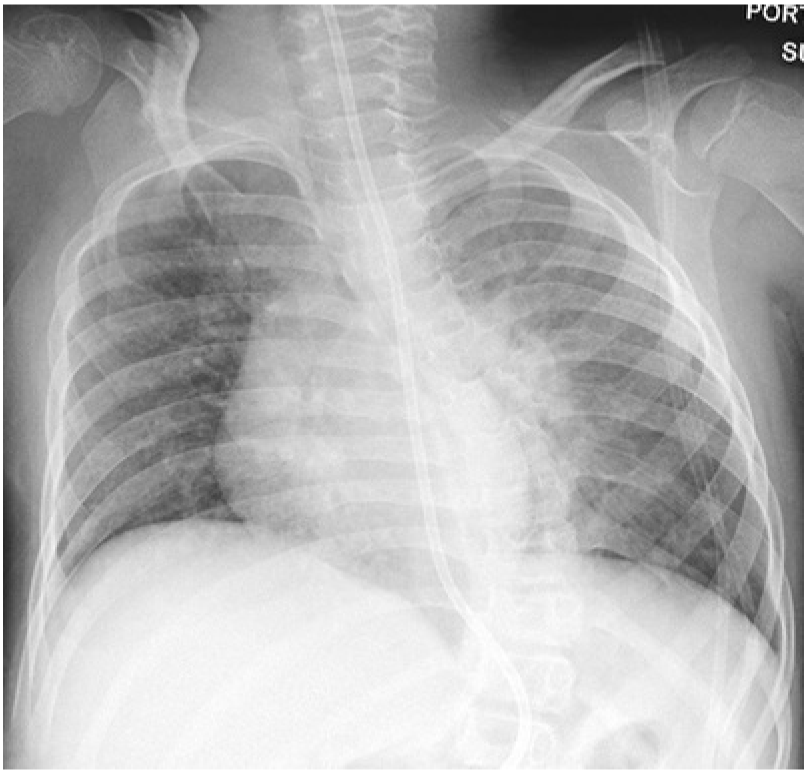

**FIG. 10.26** Chest radiograph of a 9-year-old girl with gastroesophageal reflux and chronic aspiration shows bilateral perihilar bronchial wall thickening, particularly in the upper zones (see Fig. 10.59). The apparent rotation is caused by scoliosis.

## Pneumothorax

In young children, the appearance of a pneumothorax differs from the typical adult appearance. The variation is due to differences in lung parenchymal elasticity. In children, there is often no peripheral lucent zone on supine radiographs, which is the typical appearance in adults, because in the child, gas collects anteriorly in the anterior pleural reflection (Figs. 10.27 and 10.28). Increased clarity of the cardiac outline may be the only finding, and it should be assessed carefully. If there is clinically significant doubt, a lateral shoot-through or decubitus x-ray should be performed. These are more sensitive for detecting small-volume pneumothoraces.

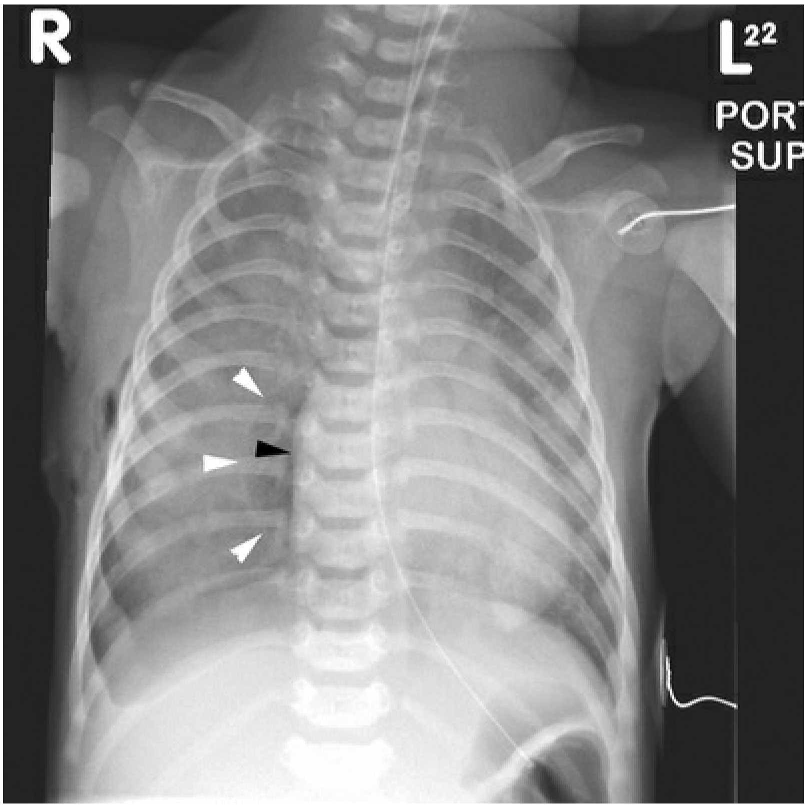

**FIG. 10.27** An anterior pneumothorax as seen typically in infants. The *white arrowheads* show the lateral boundary of the lucency. The gas adjacent to the right heart border causes a crisp outline *(black arrowhead).*

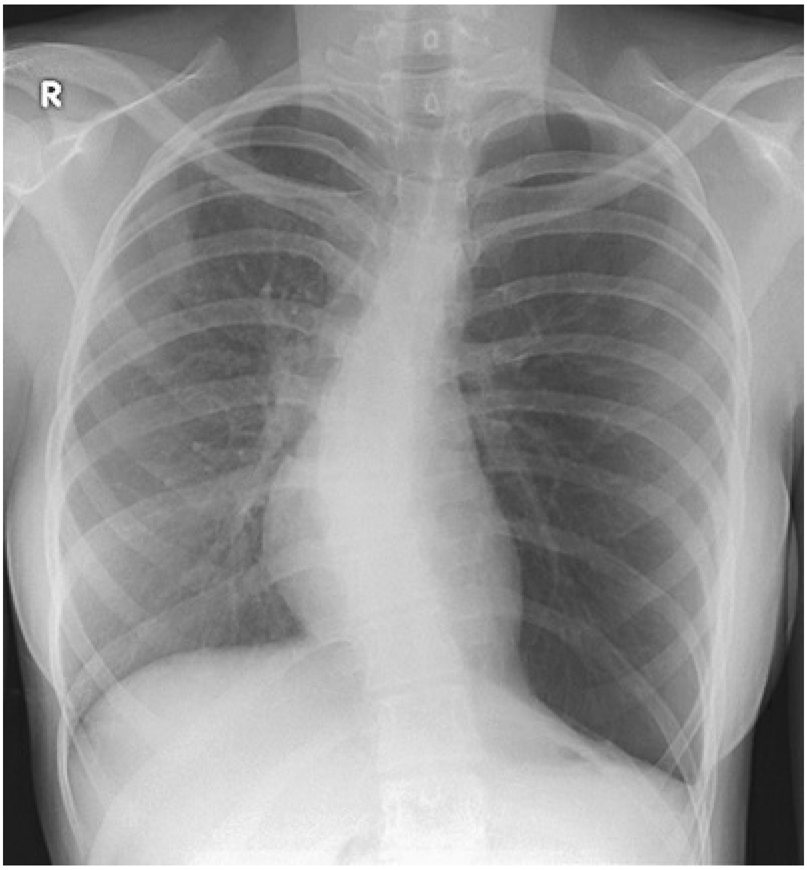

**FIG. 10.28** Chest radiograph of a 12-year-old girl shows a hyperlucent left hemothorax, inversion of the left hemidiaphragm, and a very crisp cardiodiaphragmatic outline. This is suggestive of anterior tension pneumothorax. Scoliosis is noted.

## Skeletal Abnormalities Associated With Respiratory Disorders

On conventional radiographs, undermineralization of the skeleton can be diagnosed confidently only in severe cases. Associated with prematurity, this metabolic bone condition is commonly seen in infants with idiopathic RDS. Bone mineral loss is also a feature of a multitude of constitutional disorders and may be seen secondary to systemic corticosteroid therapy.

Scoliosis may be caused by vertebral abnormalities, which may be part of the VATER (Vertebral, Anorectal, Tracheo-Esophageal, Renal/Radial malformations) or VACTERL (VATER with the addition of cardiovascular malformations) sequences, or more commonly, may be caused by neuromuscular disorders. In addition, it may be secondary to chest conditions, such as hypoplastic lung, atelectasis, or empyema, in which case the resultant spinal curvature is concave toward the side of the abnormality.

Both focal and multifocal osseous lesions may be associated findings in conditions that also involve the lungs. Well-defined lytic (“punched out”) lesions in the ribs or scapulae and the collapse of vertebral bodies are features of Langerhans cell histiocytosis. More ill-defined lesions are seen in primary neoplasms (e.g., primitive neuroectodermal tumors [PNET], previously known as Ewing/Askin tumor), lymphoma, infection (e.g., tuberculosis), or infection associated with chronic granulomatous disease. Erosion of posterior rib elements, with splaying, is seen with thoracic paraspinal neuroblastoma.

## Fluoroscopic Techniques

Limitation of radiation exposure is vital in childhood, but a quick fluoroscopic screening examination of the chest (using pulsed rather than continuous fluoroscopy) can prove extremely useful, particularly when evaluating differing lung radiolucencies in suspected foreign body aspiration and in chronic stridor.[4] With obstructive overinflation, the affected lung will show little volume change with respiration, and the mediastinum will swing contralaterally on expiration. Fluoroscopic lateral views also may be valuable for dynamic evaluation of tracheomalacia, where the trachea may be seen to collapse during expiration.

Barium swallow is still the primary study in patients with a suspected vascular ring, which abnormally indents the contrast column in the esophagus. This test may also be valuable for assessing extrinsic masses. Tracheoesophageal fistula and large laryngeal clefts can be excluded with a good-quality single-contrast study when a water-soluble contrast medium with a high iodine concentration is delivered under pressure via a nasal tube to the esophagus. The child is kept prone and screened with a horizontal beam to facilitate visualization of contrast leakage into the trachea or bronchi.

Thin-section CT has almost eliminated the need for bronchography in children; however, the technique is still used in functional studies for assessing the dynamics of intermittent airway obstruction (Fig. 10.29 and Video 10.1▶). With this technique, the mucosa of the trachea and the first to third generations of bronchi are coated with water-soluble contrast medium, which is instilled with a repeated small-bolus technique via a fine tube at the subglottic level in the intubated child.[5]

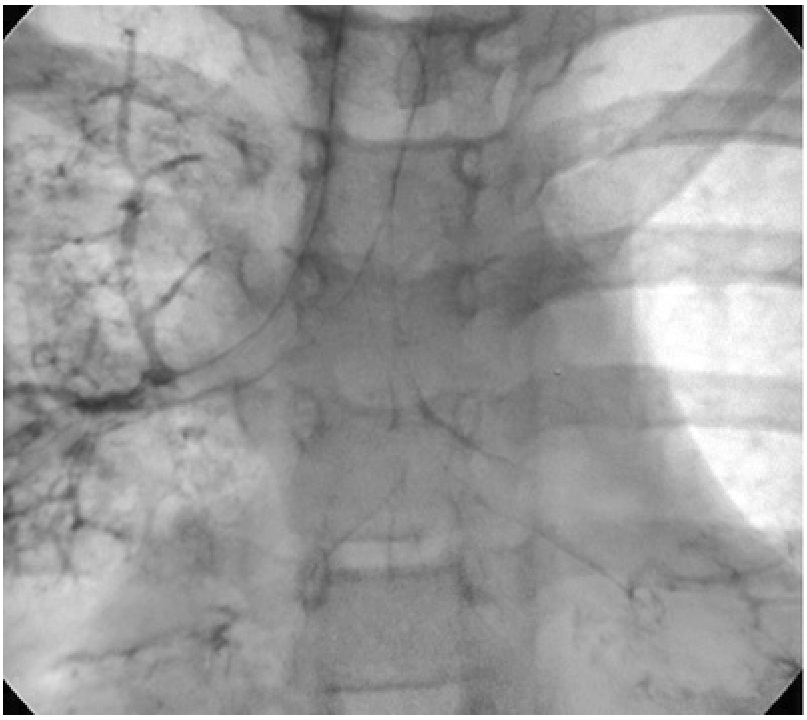

**FIG. 10.29** Bronchogram in a girl with stridor shows a long stenosis of the distal trachea, with an abnormal origin of the right upper lobe bronchus from the trachea (see Figs. 10.35 and 10.36). (Image courtesy of Dr. D. Roebuck.)

There is also a limited role for fluoroscopy in diaphragmatic assessment, although ultrasound assessment is preferred, with some authors suggesting M-mode imaging as a useful adjunct (Videos 10.6 and 10.7▶▶).

## Computed Tomography

CT is an invaluable technique in many pediatric chest diseases.[6] However, it is vital to assess the diagnostic benefit versus the potential radiation risk to the patient. CT is currently the most sensitive way of imaging the lungs due to its high spatial resolution. High-speed scanning allows for superb depiction of even small vessels after delivery of an intravenous bolus of iodinated contrast medium. In the child younger than 5 years of age, sedation or general anesthesia may be required, although recently this need has been significantly reduced with the introduction of state of the art multidetector row (MDCT) and dual-source CT scanners allowing much faster acquisition times, thus reducing the effect of respiratory, cardiac, and patient motion (Fig. 10.30).

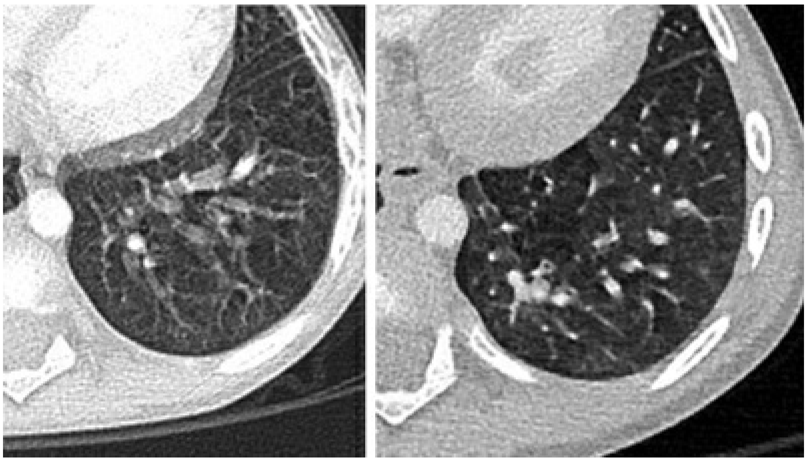

**FIG. 10.30** CT sections demonstrating the effect of increased pitch and higher temporal resolution scanning on a state-of-the-art scanner. The image on the *left* (pitch = 1) on an older scanner with lower temporal resolution demonstrates respiratory and cardiac motion artifact. These are eliminated by high-pitch, high temporal resolution scanning (pitch = 3.2) on a current state-of-the-art scanner, demonstrating focal air trapping in the medial left lower lobe (image on the *right*).

Traditional noncontiguous (interrupted/interspaced) HRCT has largely been superseded by high pitch spiral CT (Fig. 10.31).

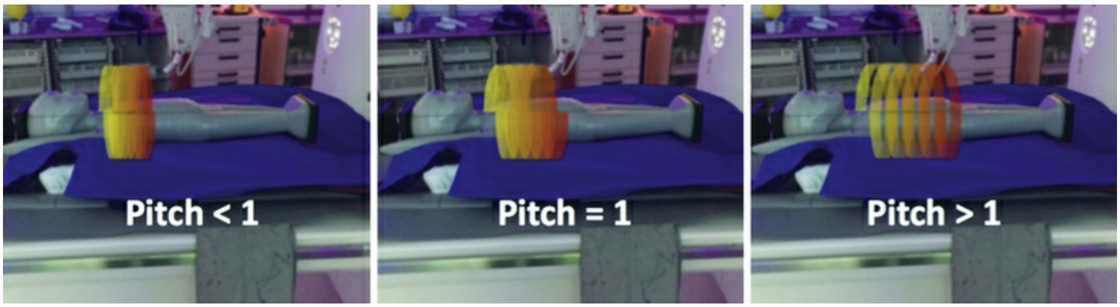

**FIG. 10.31** Explanation of computed tomography pitch. Pitch is the relationship of beam width and gantry rotation speed to rate of table movement. A pitch of less than 1 provides overlapping sections with duplicated data; a pitch of more than 1 contains gaps in which data must be interpolated, but reduces scan time and therefore motion artifact.

## Isotropic Computed Tomography

Modern MDCT scanners, with increasing number of detector rows (currently up to 320 simultaneous sections per tube rotation) and sub-second tube rotation speeds, have further enhanced performance, delivering faster scan time (improved temporal resolution) with a wider scan range. When this is combined with the use of smaller detector elements (down to 0.5 mm), this enables acquisition of isotropic volumetric datasets (where the slice thickness is equal to the pixel dimensions), resulting in improved spatial resolution in the cranio-caudal/longitudinal axis and reduced partial volume artifacts. It is now possible to acquire high-resolution thoracic CT in spiral mode in children, without breath holding and with minimal respiratory, cardiac, and patient motion artifact, with a reduced reliance on sedation and general anesthesia.

Isotropic imaging necessitates the reconstruction of overlapping thin sections that are susceptible to image noise. To overcome this, using postprocessing software, the data are manipulated into arbitrary cross-sectional planes and presented as two-dimensional or three-dimensional displays that have the same partial resolution as that of the original acquired dataset. The ability to view volumetric data in any plane enhances the interpretation and assessment of the bronchial tree and cardiovascular system. It is crucial in defining pulmonary nodules, and it allows better differentiation between organ interfaces parallel to the scan plane (e.g., the horizontal fissure) to aid diagnostic accuracy.

These benefits have dramatically expanded the application of CT in the evaluation of cardiovascular and airway diseases. MDCT is now commonly used in place of conventional angiography because the images are acquired more safely, without the need for arterial puncture, and often, given the very rapid acquisition times (2–8 seconds), without the need for general anesthesia or sedation. The additional benefit over angiography is that superb anatomic images of the mediastinum and lung parenchyma are acquired in the same data set, without additional radiation. The overall radiation dose in MDCT is significantly lower than that in conventional angiography. Thus, MDCT can aid in the diagnosis of pulmonary embolus, arteriovenous malformation, aneurysm, and dissection. However, unlike MDCT, conventional angiography has the advantage of allowing therapeutic intervention in the same procedure. Images of the airway acquired simultaneously can ascertain the presence of airway stenosis and narrowing as well as show the causes of possible extrinsic compression.

## Data Processing

Depending on the clinical application, the acquired volumetric data can be reformatted and displayed as a two-dimensional image using multiplanar reconstruction (MPR) and multiplanar volume reconstructions, known as maximum intensity projections (MIP) or minimum intensity projections (MinIP). The techniques used to display three-dimensional images include volume-rendering technique (VRT) and perspective rendering (e.g., virtual bronchoscopy [VB]).

### Multiplanar Reconstruction

MPRs are two-dimensional tomographic sections manipulated by the operator into an arbitrary imaging plane (i.e., the coronal, sagittal, or arbitrary angulated planes) or into a single tomographic curved plane along the axis of a structure of interest (e.g., a bronchus or a tortuous vessel).[7,8] Slice thickness of the MPR is operator-dependent, and increasing the thickness will improve the signal-to-noise ratio. MPR enhances the perception of the image, provides additional diagnostic value in demonstrating the presence of small focal lesions (e.g., defining the vertical extent of a bronchial stenosis) (Fig. 10.32), and is often used in the presurgical assessment of vascular rings and the tracheobronchial tree.[9]

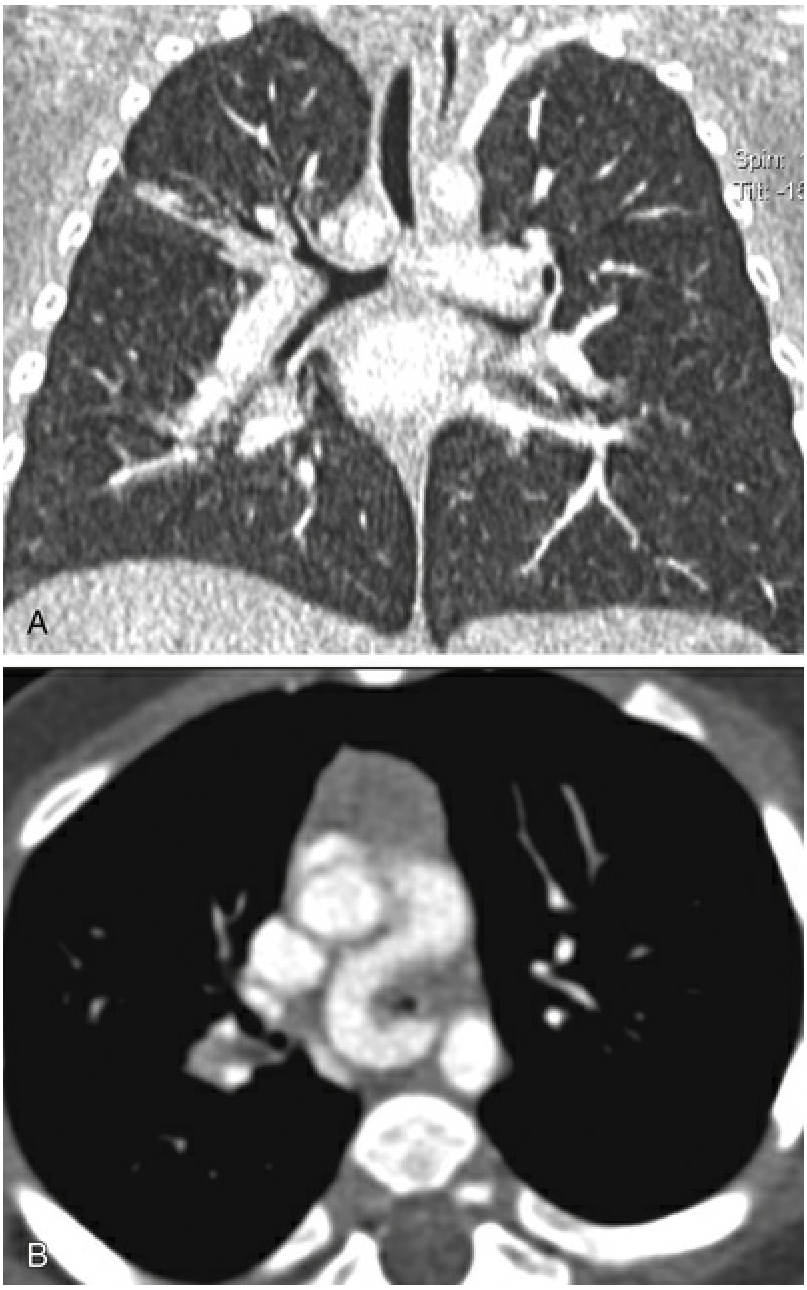

**FIG. 10.32** Coronal multiplanar reconstruction (MPR) (A) and axial maximum intensity projection (B) images in a 5-month-old child presenting with stridor. There is

tracheal stenosis caused by the presence of a pulmonary sling with almost complete occlusion of the distal trachea with marked narrowing of the left main bronchus (LMB) origin related to the aberrant left pulmonary artery, which has an anomalous origin from the right pulmonary artery, passing behind the trachea and in front of the esophagus. Cartilaginous rings were not identified in this examination. The coronal MPR image (A) has been postprocessed on a high-resolution (bony) algorithm more suitable for viewing lung parenchyma but giving a more “noisy” (i.e., grainy) image.

## Multiplanar Volume Reconstructions: Maximum Intensity Projection and Minimum Intensity Projection

MIP is a rendering tool used to extract contrast-enhanced anatomic structures of higher attenuation values than adjacent structures, as in CT angiography (Fig. 10.33 and Video 10.1▶). The data are displayed in volume slabs to avoid obstruction from overlying vessels or bony structures. These thicker slabs are useful in depicting the peripheral airway, detecting and localizing micronodular or microtubular patterns, and analyzing mild forms of uneven attenuation of the lungs.[10] On the other hand, MinIP displays structures with the lowest attenuation values used in demonstrating the central airway and air trapping in the lungs (Fig. 10.34 and Video 10.2▶).

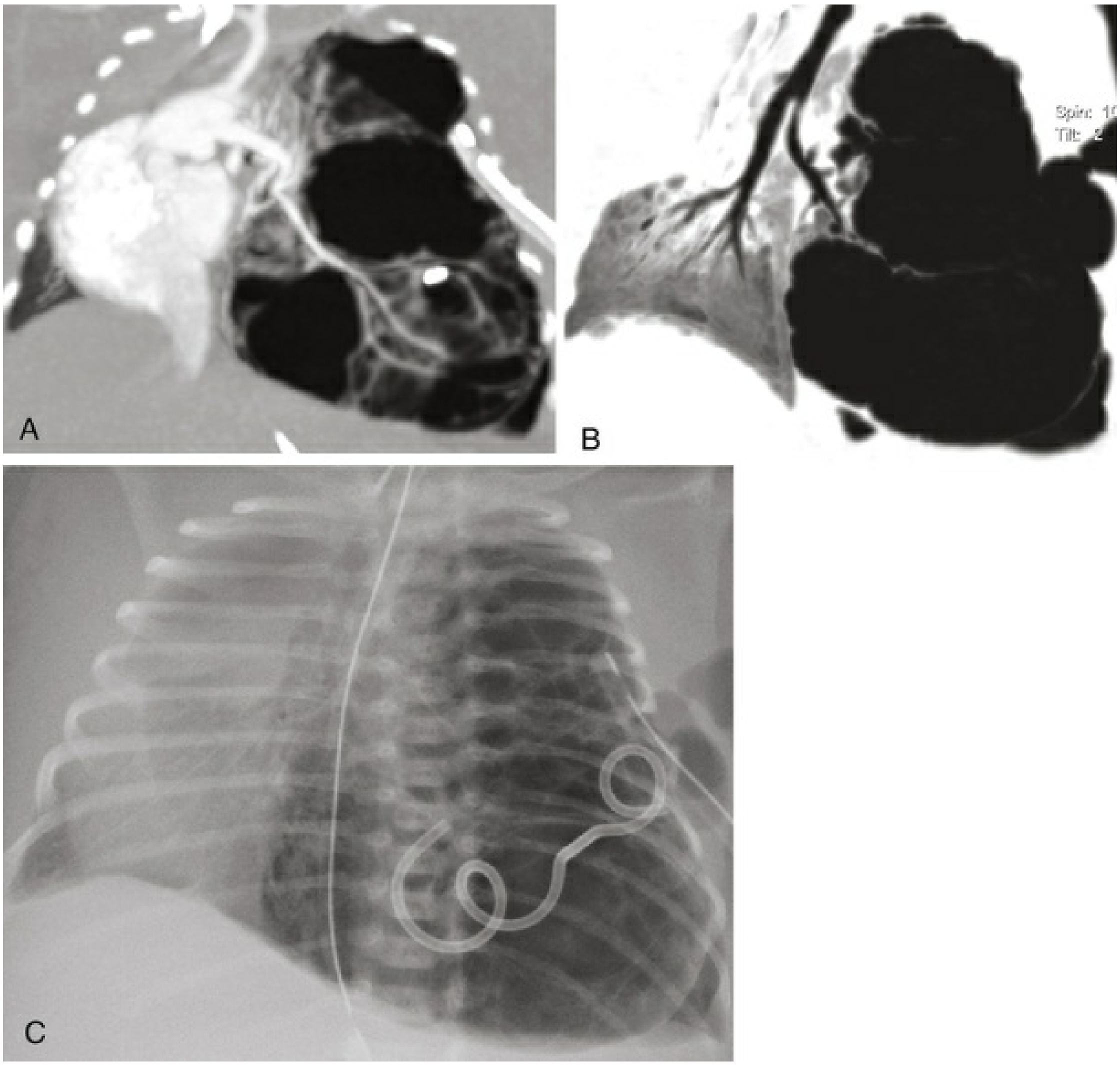

**FIG. 10.33** Multiloculated air-filled cystic mass in a 4-day-old neonate with an antenatally diagnosed congenital thoracic malformation treated with antenatal drainage; see catheter on chest x-ray (C). (A) Maximum intensity projection image, where data with maximum intensity (contrast) is aggregated thus enhancing the blood supply. A branch pulmonary artery can be seen supplying the left lower lobe. (B) Minimum intensity projections, where data with lowest intensity (air) is combined to highlight the tracheobronchial tree emphasizing the very dilated cystic acinar units in the lung parenchyma and the abnormal ptosed and narrowed LMB. The chest radiography in (C) shows the enlarged hyperlucent left lung with herniation across the midline causing compression and shift of the mediastinum and right lung (which is atelectatic). Note the coiled left intrathoracic pigtail drain that was placed antenatally.

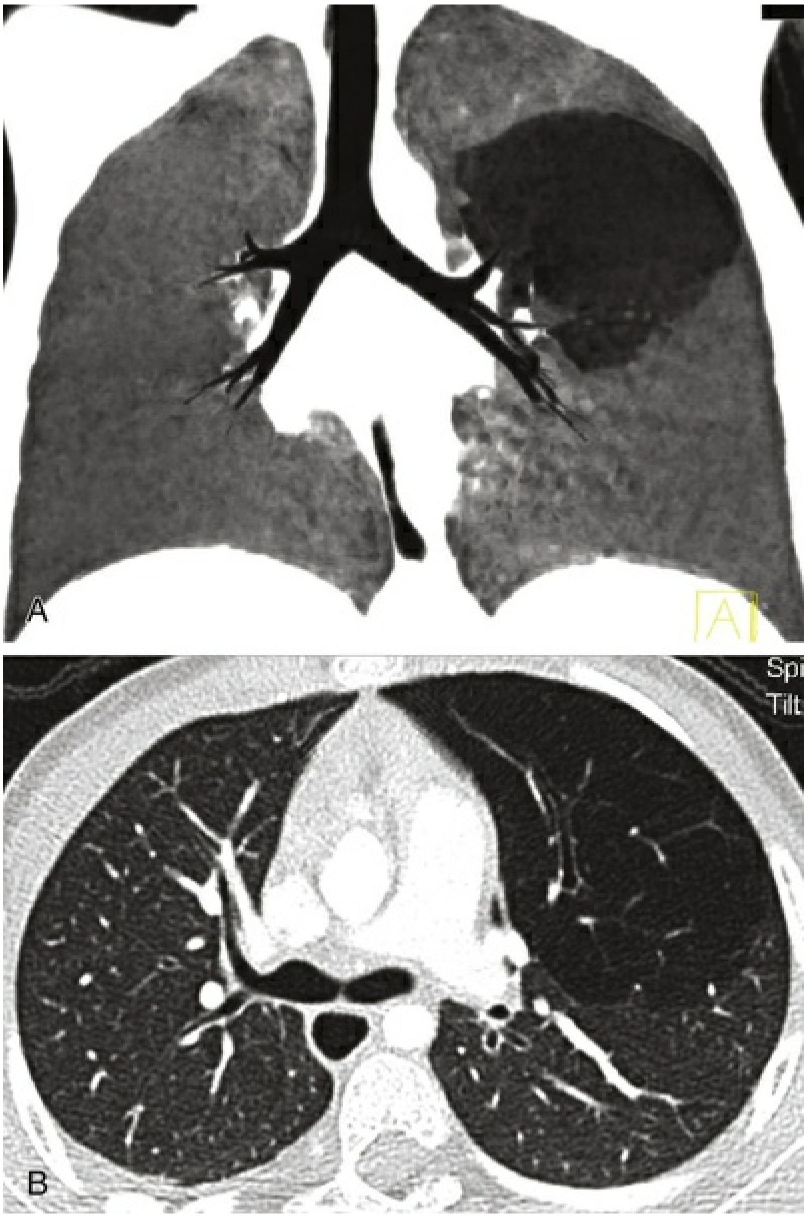

**FIG. 10.34** A 5-year-old child with segmental left upper lobe (LUL) overinflation. The coronal thin minimum intensity projections (A) shows a well-defined anterior segmental area of regional air trapping in relation to segmental overinflation. A thin axial section (B) shows the lung parenchyma anatomy in the most favorable setting. Note the clarity of the definition of the bronchial wall and adjacent pulmonary artery branch within the hyperlucent segment of the LUL.

## Volume-Rendering Technique

VRT is a processing technique (used for interpreting CT angiography, CT bronchoscopy, and orthopedic imaging datasets) that utilizes all acquired volumetric data without being subject to information loss. This is in order to display an image in a three-dimensional format so that the image can be further manipulated and viewed in different orientations (Fig. 10.35).

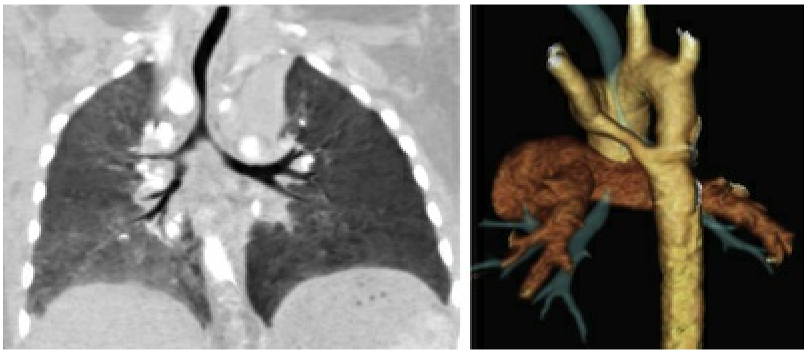

**FIG. 10.35** Coronal minimum intensity projections computed tomography image and volume-rendering technique (viewed from a posterior perspective) demonstrating a double aortic arch, with a dominant right arch, forming a vascular ring with resultant tracheal compression. There is also compression of the main bronchi at the level of the pulmonary arteries. Note the particularly tight left bronchial compression with decreased attenuation in the left lung consistent with air trapping.

VRTs are used to depict structural and vascular anatomy (Fig. 10.36) and their relationship to adjacent structures, and to displaying structures that course parallel or oblique to the transverse plane (and also those that develop or extend into multiple planes).[7,8] Applying a transparency filter highlights the tracheobronchial tree, which, in turn, better illustrates short focal areas of narrowing, the craniocaudal length of a tracheobronchial stenosis, and other tracheobronchial anomalies. The mediastinal vasculature is best displayed as color-coded opacifications used for evaluating complex congenital cardiovascular anomalies (Video 10.4).

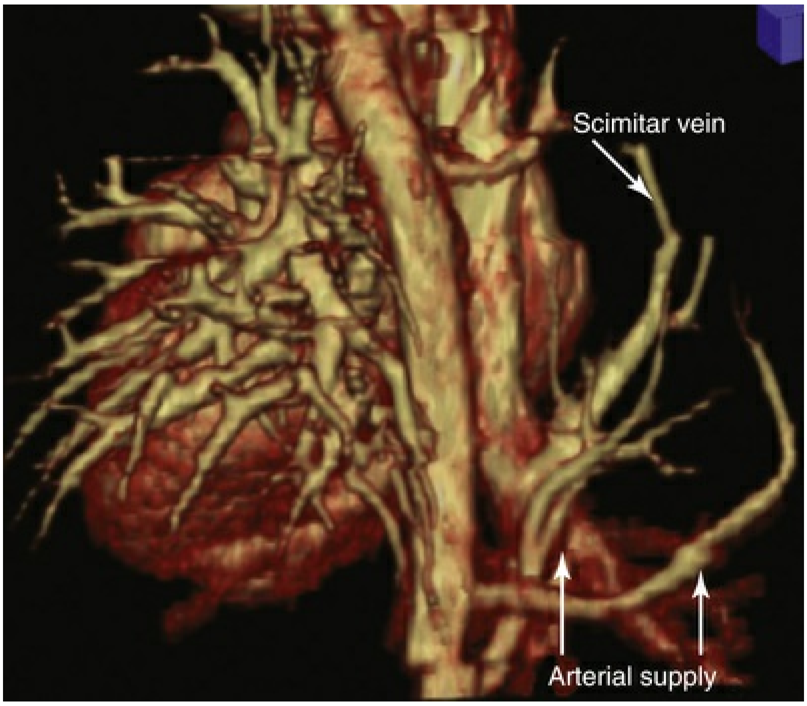

**FIG. 10.36** Volume-rendering technique image of a 4-year-old child. A scimitar vein is seen joining the suprahepatic portion of the inferior vena cava (IVC) inferior to the right atrium. The systemic artery arises from the descending aorta and supplies the right lung.

## Virtual Bronchoscopy

VB is a perspective surface-rendering technique that takes advantage of the natural contrast between the airway and the surrounding tissues,[9] mimicking a bronchoscopic view of the intraluminal surface of the air-containing tracheobronchial tree (Fig. 10.37 and Video 10.5). VB provides an additional viewing dimension; the operator can navigate along the lumen of the airway, where bronchial surfaces can be visualized, and even across obstructions that an endoscope cannot traverse.[7,11] This technique is used when bronchoscopy is contraindicated or when tracheal stenosis cannot be otherwise evaluated.[12] Although dynamic VB can technically be used, virtual bronchography is more valuable.

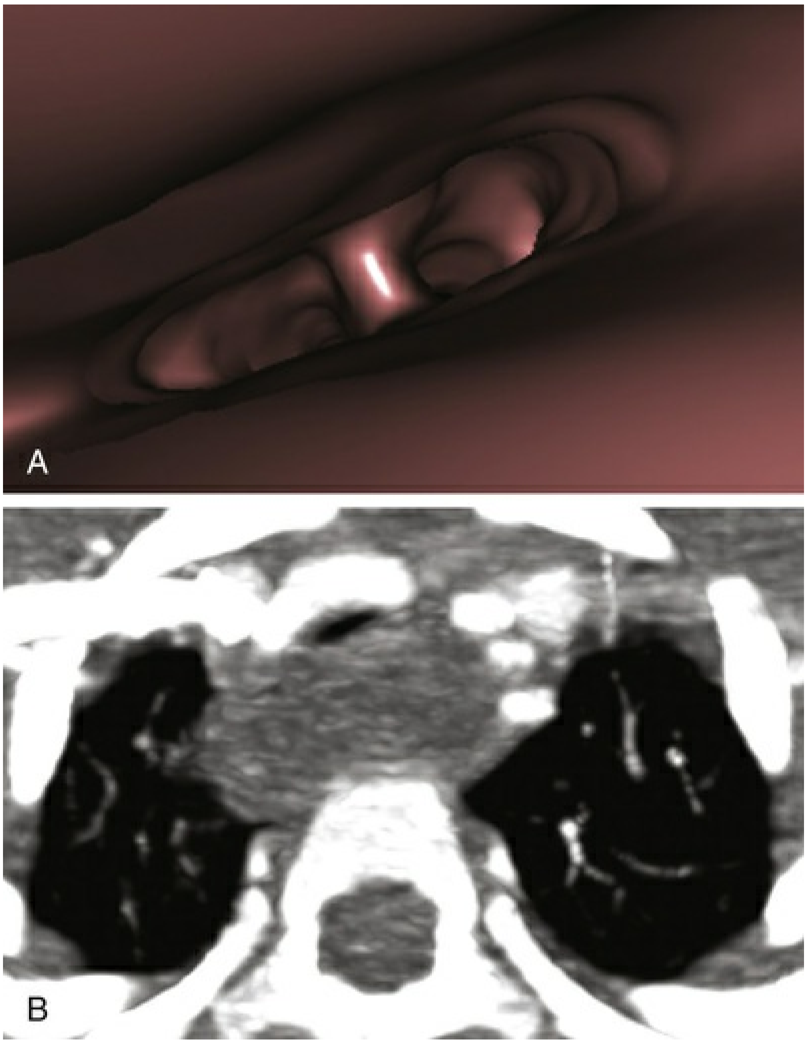

**FIG. 10.37** This 2-year-old child presented with tracheal stenosis. The virtual bronchoscopy (A) demonstrates a dramatic anteroposterior (AP) narrowing of the trachea at the level of the carina, which is compressed by an enlarged esophagus posteriorly (diagnosed as achalasia of the esophageal cardia on barium study), as seen in (B).

## Further Advanced Postprocessing

Postprocessing software packages are beginning to include more advanced tools allowing further data extraction. While many of these techniques remain to be validated against established measurements, especially in children, they hold promise for future areas of research and clinical practice. Examples include automated segmentation algorithms allowing the measurement of lung volumes, low attenuation mapping potentially enabling quantification of regions of air-trapping, and automated methods of quantification of airway thickening and bronchiectasis (Figs. 10.38–10.40).

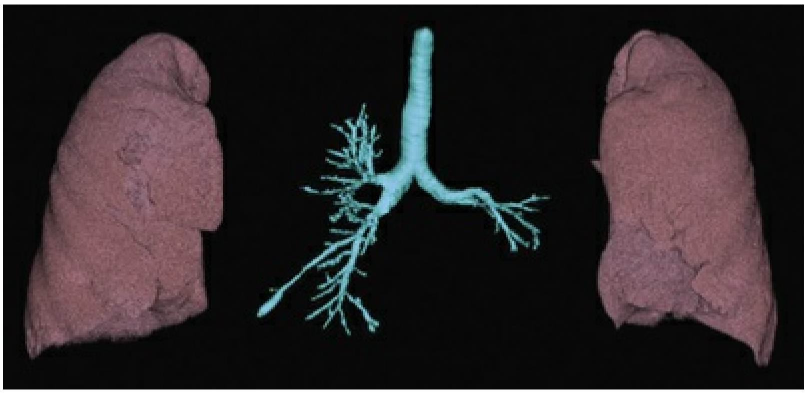

**FIG. 10.38** Automated segmentation—automatically segmented lung and airway volumes allowing quantification structural volume—for example, lung volume measurement prior to transplantation and potential quantification of bronchiectasis in cystic fibrosis.

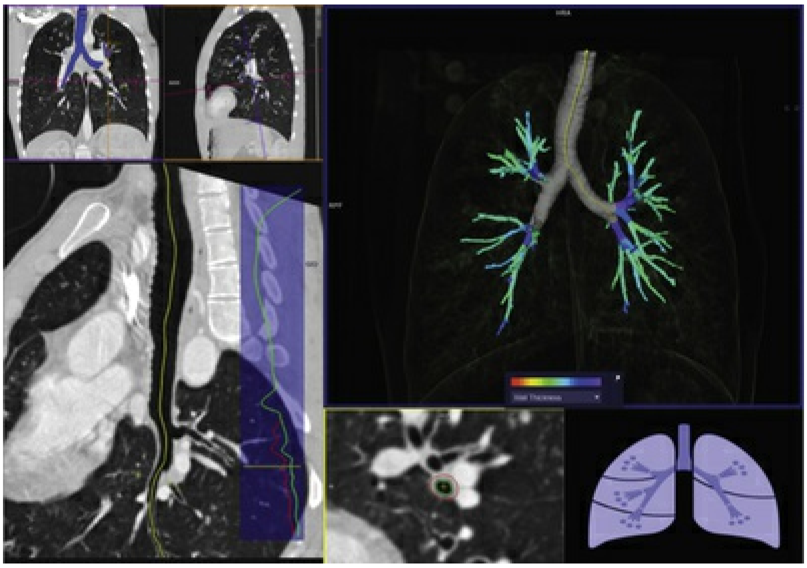

**FIG. 10.39** Automated airway wall thickening measurement (measured between the *green* and *red circles* with thickness represented by a color scale in the three-dimensional reconstruction on the *top right*). Images produced using Syngo.Via, Siemens

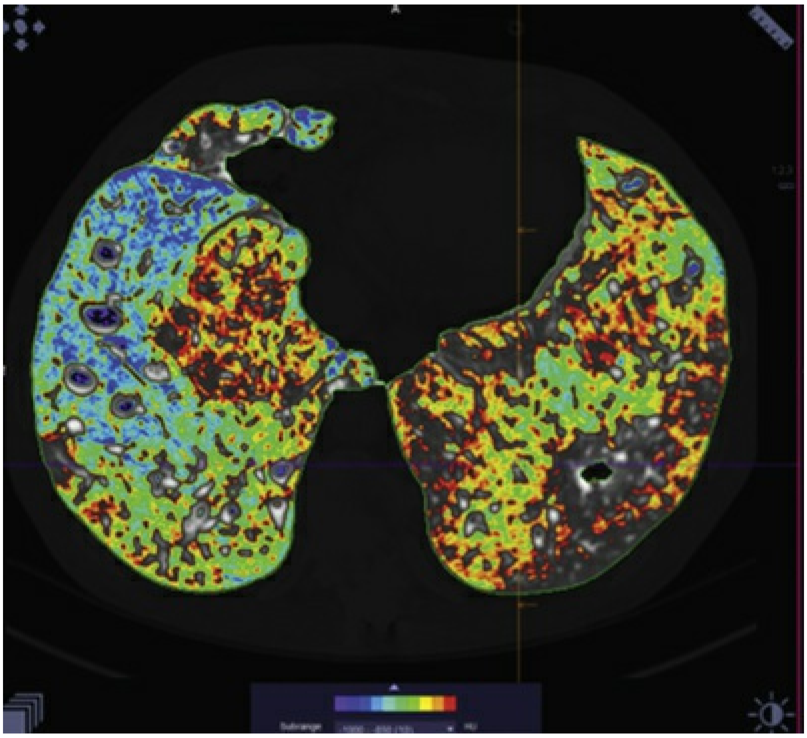

**FIG. 10.40** Low attenuation map image through the lung bases of a patient with cystic fibrosis. Note the air-trapping (in *blue*) around the dilated, thick-walled, air-fluid level containing bronchi. This technique allows the calculation of the total volume of lung of each attenuation value range, thus providing a potential marker of the extent of air-trapping.

## Review of Findings

The interpretation of findings requires a systematic review of all anatomic structures and areas, including those shown in Table 10.2 and Figs. 10.41–10.50.

### Table 10.2

### Main Review Areas for Spiral Computed Tomography of the Chest

| Structure/Area | Abnormalities |
|---|---|
| Airways | Extrinsic compression (see Figs. 10.41 and 10.42) |
| | Caliber change |
| Vessels | Vascular rings |
| | Aberrant vessels |

| | |
|---|---|
| Anterior mediastinum | Thymic enlargement, nodularity, heterogeneous enhancement |
| Middle mediastinum | Enlarged lymph nodes |
| | Bronchopulmonary foregut malformations (see Fig. 10.43) |
| | Cardiac abnormalities |
| Posterior mediastinum | Benign lesions: Duplication cyst, meningocele, ganglioneuroma, abscess, extramedullary hematopoiesis |
| | Malignant lesions: Neuroblastoma |
| Hila | Enlarged lymph nodes |
| Lung parenchyma | Lung/lobar aplasia, agenesis, hypoplasia, overinflation (see Figs. 10.44–10.47) |
| | Focal lesions: Nodules, consolidation, atelectasis (see Fig. 10.48) |
| Pleura | Transudate, exudates, pus, hemorrhage, lymph (see Fig. 10.50) |
| Chest wall and spine | Osseous or soft-tissue lesions: Infection, benign and malignant tumors |
| | Abnormal configuration: Scoliosis, pectus deformities |
| Upper abdomen | Lesions of the liver, spleen, adrenal glands, and upper poles of kidneys |
| | Retroperitoneal, peritoneal, and abdominal wall lesions |

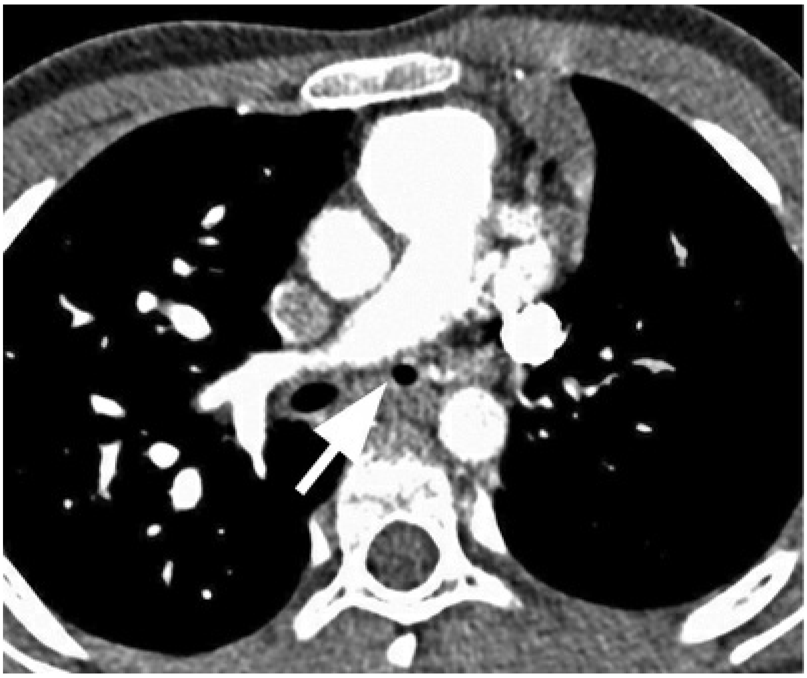

**FIG. 10.41** On arterial phase computed tomography of the same girl as in Fig. 10.29, there is narrowing of the left main bronchus *(arrow)* where it passes between the right pulmonary artery and the descending aorta, which was found to represent an intrinsic defect due to complete cartilaginous rings.

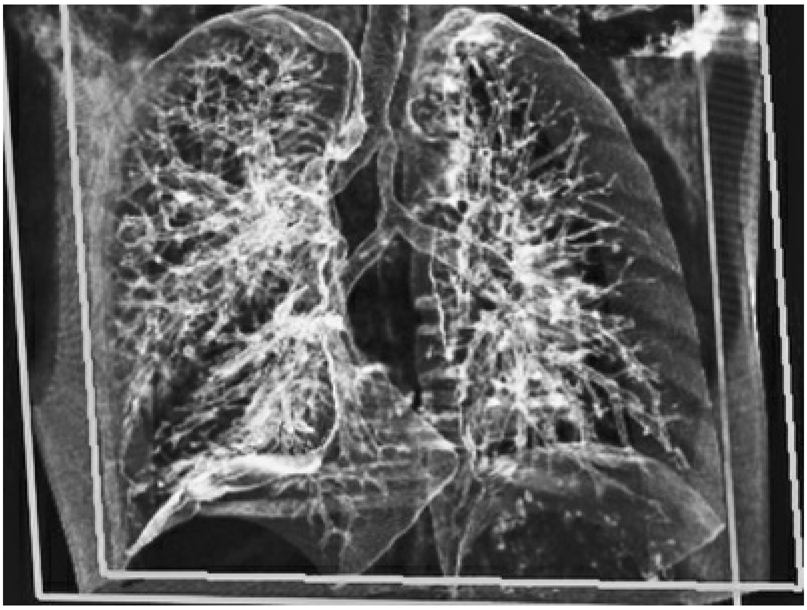

**FIG. 10.42** Volume-rendering of computed tomography volume data in the same child as in Figs. 10.29 and 10.41 shows the anatomy of both the central and peripheral airways, with distal tracheal stenosis.

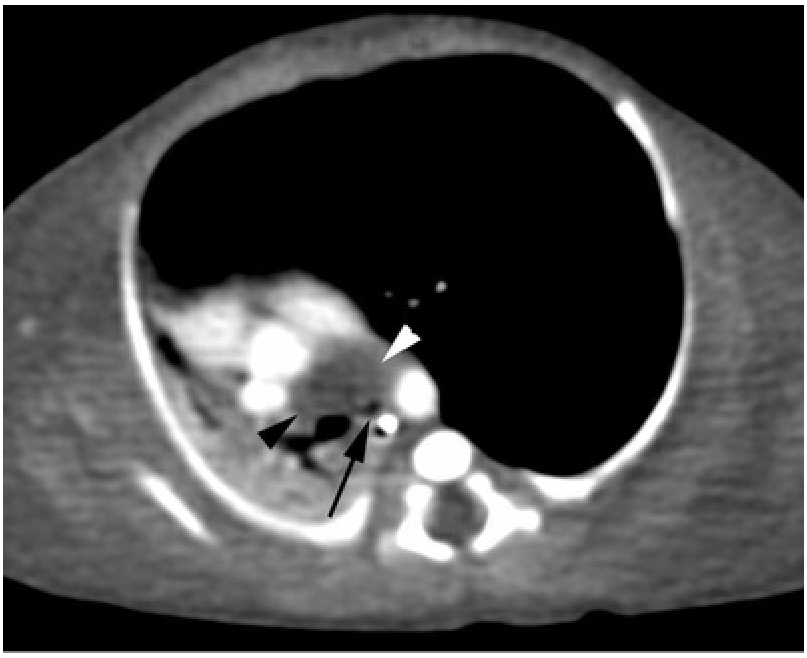

**FIG. 10.43** Contrast-enhanced spiral computed tomography shows a precarinal bronchogenic cyst *(arrowheads),* with associated narrowing of the left main stem bronchus *(arrow),* a hyperinflated left lung, and a collapsed right lung (see Fig. 10.7).

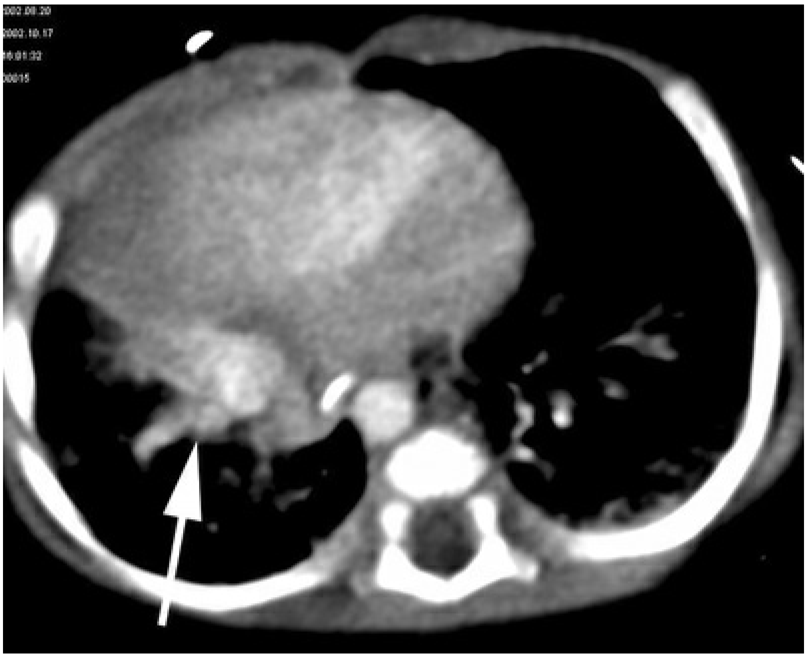

**FIG. 10.44** Contrast-enhanced spiral computed tomography shows systemic venous drainage of the hypoplastic right lung into the right atrium (*arrow;* see Figs. 10.5 and 10.46).

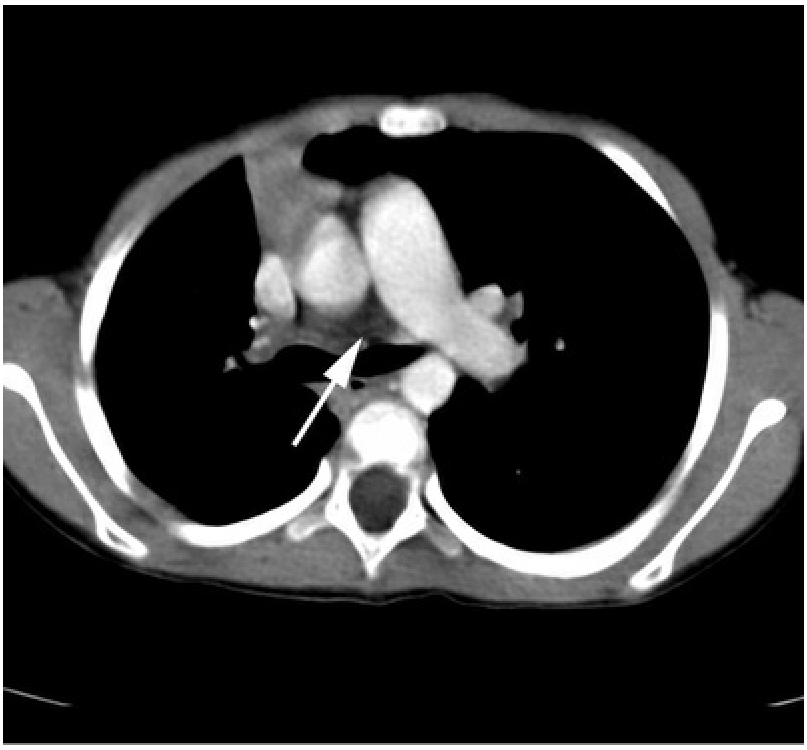

**FIG. 10.45** Contrast-enhanced computed tomography through the mediastinum shows a small right lung and no enhancement in the normal site of the right

pulmonary artery *(arrow).* Because the right pulmonary artery is absent, the right lung must receive a systemic supply; however, the collaterals cannot be seen (see Figs. 10.4 and 10.70).

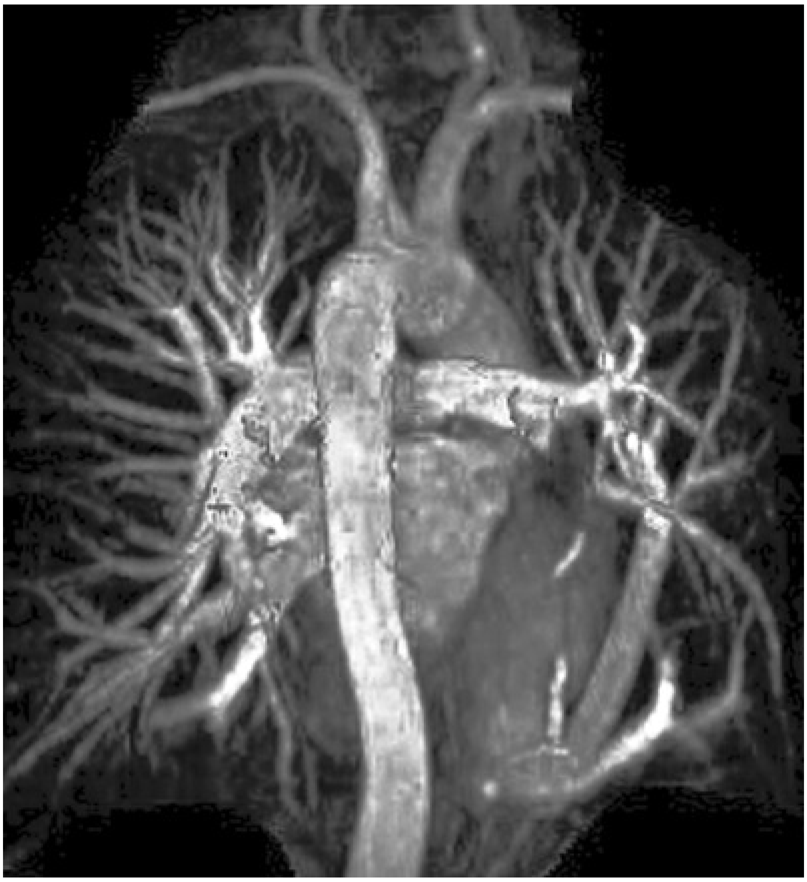

**FIG. 10.46** Three-dimensional magnetic resonance imaging scan shows the infra-atrial drainage of a scimitar vein (*arrow,* posterior view; see Fig. 10.5 and 10.44).

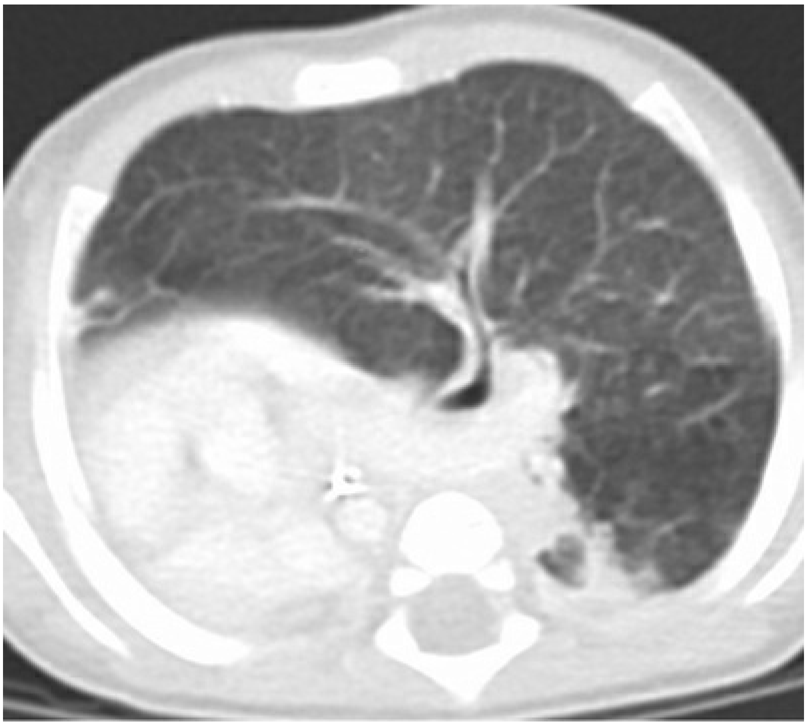

**FIG. 10.47** Contrast-enhanced computed tomography shows agenesis of the right lung and compensatory increased volume of the left lung, which appears structurally normal (see Fig. 10.6).

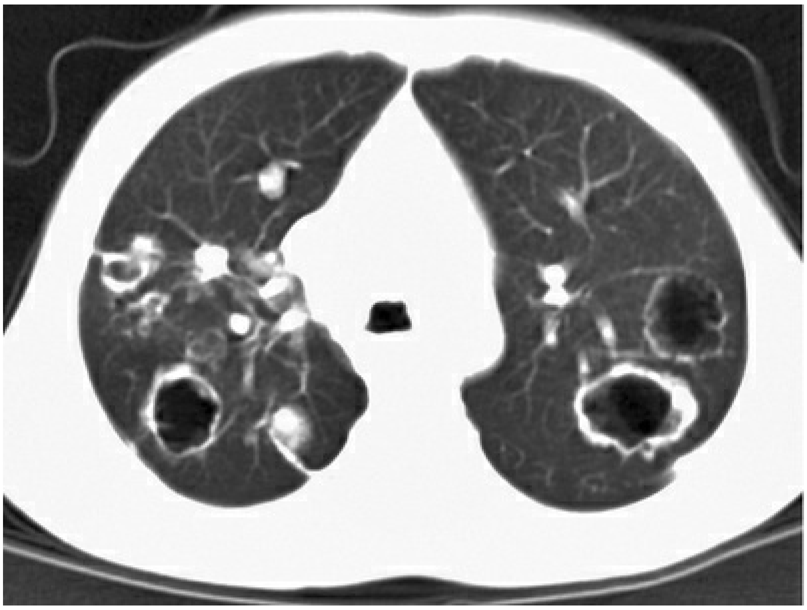

**FIG. 10.48** Chest computed tomography of an 8-year-old girl with laryngotracheal papillomatosis shows multiple peripheral nodules and cavities with posterior dominance, in keeping with pulmonary dissemination (see Fig. 10.17).

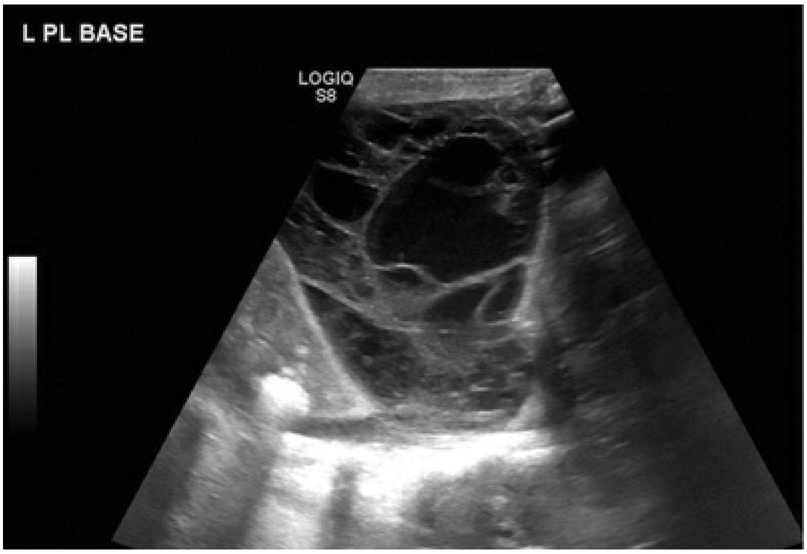

**FIG. 10.49** Ultrasound image demonstrating an extensively septated pleural collection (empyema) with collapse and consolidation of the underlying lower lobe, which contains an echogenic round focus posteriorly, possibly representing gas within a pulmonary abscess cavity.

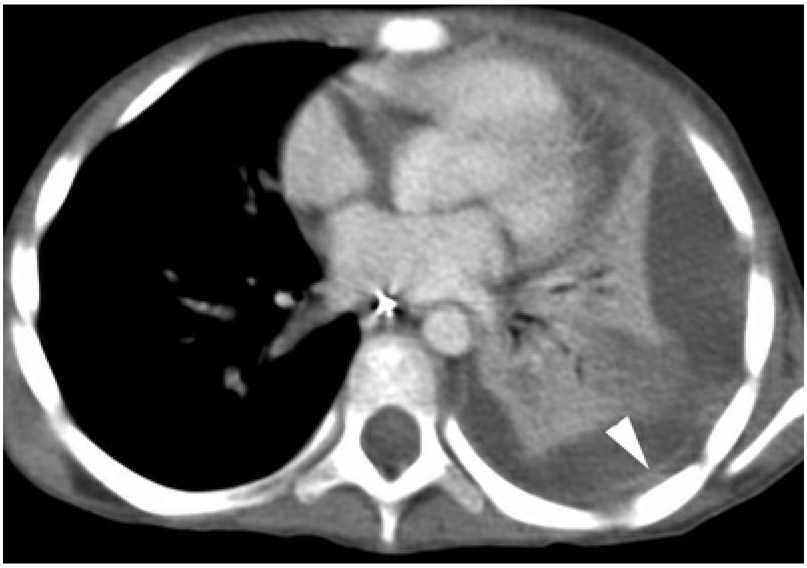

**FIG. 10.50** Contrast-enhanced computed tomography (CT) confirms the ultrasound finding of consolidated lung (note air bronchograms) and pleural fluid. There is mild pleural thickening and enhancement that is

nonspecific *(arrowhead).* CT did not show calcification. Acid-fast bacilli were cultured from the pleural fluid. This case shows the currently nonspecific role of CT in the imaging of pleural fluid (see Fig. 10.51).

Axial depiction of pulmonary parenchymal anatomy and abnormalities with spiral CT is slightly inferior to that depicted with traditional interspaced HRCT. On the other hand, the spiral scan covers the whole volume of the lungs with no gaps and is therefore more sensitive for demonstrating small solitary lesions, such as small metastases or fungal lesions.

CT performs poorly in differentiating between pleural effusion and empyema.[13] Pleural thickening and enhancement are often present in reactive effusions. Plain radiography, followed by ultrasound, is the investigation of choice because ultrasound has the ability to visualize the fibrinous septations of an infectious process (see Fig. 10.49).

However, CT is useful in distinguishing between empyema and lung abscess. Empyema shows a wide pleural base (see Fig. 10.50), whereas a lung abscess is usually seen partially separated from the pleura, with a wedge of lung on either side in the imaging plane.

## Pitfalls

Technical factors may confound interpretation. Some artifacts may impede detection of significant lesions. In young children, there is invariably some degree of dependent lung opacification. This is often further exacerbated when general anesthesia or sedation is employed. When the distinction between atelectatic lung and nodular change is difficult, it may be helpful to repeat a few slices of the scan with the child in the prone position. Streak artifacts may be seen, which are caused by high-concentration contrast medium in the innominate vein at the site of delivery. This may degrade the imaging of structures in the upper mediastinum. The addition of a “saline chaser” to contrast injections, via a high-pressure pump, has been employed to reduce this phenomenon. The peridiaphragmatic areas also can be difficult to assess, as soft tissue lesions can be difficult to distinguish from the diaphragm in the transaxial plane.

Therefore, whenever possible, multiplanar reconstructions in the coronal and sagittal planes should be reviewed.

Some artifacts mimic pathology. Tachypnea or motion will inevitably blur the final image, and this phenomenon is easily confused with ground-glass change. Apparent (pseudo) bronchiectasis in the lingula and right middle lobe may sometimes be simulated by cardiac motion in which a single airway branch is represented twice in the image.

# Radiation Dose

Radiation dose considerations are particularly important in pediatric imaging. CT delivers the largest radiation burden of all diagnostic imaging modalities except for a limited number of nuclear medicine tests. Therefore its indications should be carefully considered and the scan protocol optimized to produce sufficiently diagnostic images while keeping the radiation dose as low as reasonably achievable.[15,16]

Pediatric scanning parameters should be optimized and adjusted according to patient size, based on body weight, diameter, or the region of interest. Reducing the tube current (mA) and/or tube potential (kV) will reduce the radiation dose; this is because the dose is directly proportional to the tube current and is exponentially related to kVp, so that a reduction in kV from 120 to 100 can further reduce the dose by 30%–70%.[17,18] In fact, it is preferable (in angiographic chest CT imaging) to use a lower kV as it enhances the CT attenuation of iodinated contrast, thus increasing the contrast-to-noise ratio in the perfused structures and improving overall image quality while minimizing dose.

It is widely accepted that dose reduction is associated with an increase in image noise. Air within the lungs provides high contrast with adjacent soft tissue, affording chest imaging a higher tolerance of image noise. However, a regular optimization program involving radiologists, medical physics experts, and radiographers is essential to ensure each exposure remains sufficient to produce diagnostic quality imaging.

Another method of dose reduction is the use of automatic exposure control (AEC) that is now a common application in

MDCT. The aim of AEC is to modulate the tube current according to patient-specific attenuation that ultimately reduces dose without degrading image quality.[19] However, this technique still requires adjustment of parameters to patient size to ensure dose optimization. Three basic methods of tube current modulations are used in AEC, with different manufacturers adopting a different methodology, or a combination of the three that includes: (1) patient-size modulation, (2) z-axis modulation, and (3) rotational or angular modulation.

Scanner detector configuration and use of beam-shaping filters also affect dose efficiency. Scanners that use a matrix array detector configuration (equal width of all detector rows) are less dose-efficient than those using adaptive array detectors (outer rows wider than inner rows), with greater beam utilization and reduced penumbra.

Depending on the collimation (e.g., slice thickness of 0.6 or 1.2 mm with a 64-slice scanner), tube current, and longitudinal length of the scan, the absorbed dose varies in equivalence to between 25 and 50 chest radiographs for a 2-month-old infant. In pediatric applications, the tube current should be substantially reduced, and image quality usually can be dropped (lower signal-to-noise ratio) without loss of relevant diagnostic information. Data from a recent audit of CT dose at our institution are presented in Tables 10.3 and 10.4. Comparison of computed tomography (CT) doses (volume CT dose index [CTDIvol], dose length product [DLP], and whole body effective dose) from CT thorax examinations with intravenous contrast on older (see Table 10.3) and newer (see Table 10.4) dual-source CT scanners from the same manufacturer (Siemens, Erlangen, Germany). The newer dual-source scanner is capable of high-pitch, high temporal resolution imaging compared to the previous dual-source machine with lower pitch and temporal resolution capabilities.

**Table 10.3**

# High-Resolution Computed Tomography

HRCT is the modality of choice in suspected interstitial lung disease. It allows a detailed structural assessment of secondary pulmonary lobules and intrapulmonary interstitium, thereby aiding the diagnostic workup. HRCT usually allows a confident radiologic diagnosis in cases of alveolar proteinosis, pulmonary lymphangiectasia, and idiopathic pulmonary hemosiderosis.[20] It can be used to guide lung biopsy and thoracoscopic procedures, targeting areas of active disease. HRCT allows early detection of diffuse pulmonary parenchymal disease to the level of the secondary pulmonary lobule, and is useful in the characterization of opportunistic infection in the immunocompromised patient. Serial imaging may be useful in monitoring disease activity.

The recommended technique in children with diffuse pulmonary disease includes high-pitch spiral CT from the lung apices to the lung bases, reconstructed to 1 mm sections using a high spatial resolution reconstruction kernel. If possible, in cooperative children (>5 years), CT slices should be obtained at full inspiration to diminish vascular crowding, particularly in the dependent areas of the lung, where atelectasis is more common in children than in adults. In certain circumstances three extra slices through the lung apices, mid-zones, and bases are added to the scan protocol in an expiratory phase for looking at small airways disease. In infants and small children unable to follow breathing instructions, lateral decubitus positioning can be employed with the dependent lung relatively expiratory due to gravity.

Knowledge of the anatomic basis for HRCT is a prerequisite for understanding abnormal features. Supplying arterial and bronchiolar branches pass in the core of the secondary pulmonary lobule, and draining veins and lymphatics in the connective tissue between lobules—the interlobular septa. The subpleural interstitium connects to the interlobular septa, constituting the peripheral fiber system. The bronchovascular interstitium extends centripetally from the hila.

## Controlled Ventilation Technique

A method for noninvasive controlled ventilation in sedated children may be particularly useful in HRCT. Positive pressure is applied at a facemask, and the pressure applied adjusted by changing the setting of a pressure pop-off valve. Respiratory pauses are induced by means of a step increase in ventilation combined with rapid lung inflation at a pressure of 25 cm water, given synchronously with spontaneous tidal inspiration. Lung inflations are repeated approximately three to six times until a respiratory pause occurs. Inspiratory or expiratory scans then can be acquired with minimized motion artifact.[21] However, it should be noted that the advent of high-pitch spiral scanning has largely eliminated the requirement for controlled ventilation techniques outside of research studies employing postprocessing techniques that are dependent on strict standardization of image acquisition protocols.

## Interpretation

Interpretation of HRCT images is based on the presence and distribution of certain findings (e.g., septal thickening, ground-glass change, nodular change), which may represent a variety of histopathologic processes.

## Regional or Generalized Increased Density

Consolidation (Fig. 10.51) and atelectasis may appear alike on plain radiographs, as discussed earlier. On HRCT, subsegmental atelectasis may be recognized by the traction it exerts on adjacent bronchi (traction bronchiectasis).

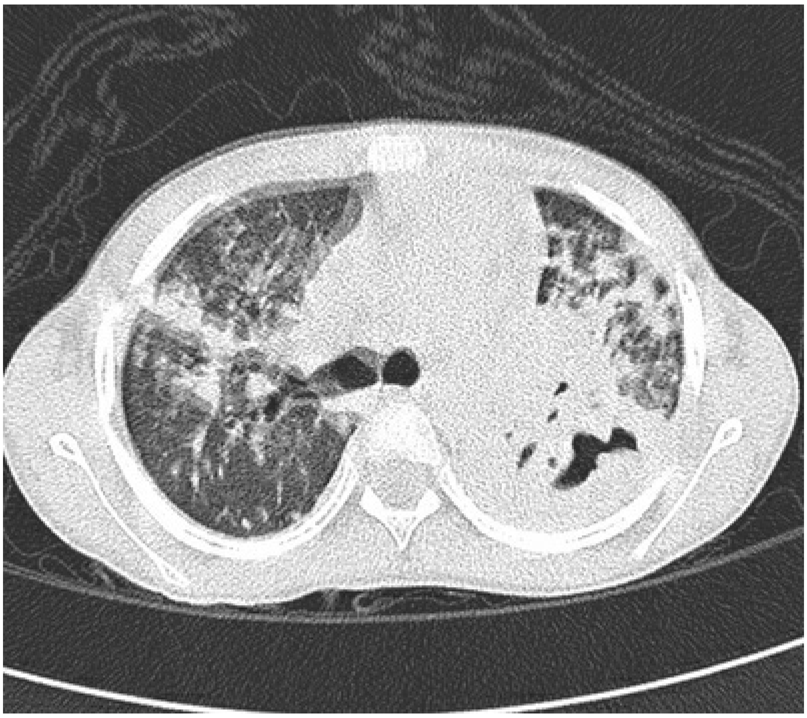

**FIG. 10.51** High-resolution computed tomography at a higher level in the same child as in Fig. 10.50 additionally shows cavitation within the left upper lobe consolidation. This was later proven to be due to *Mycobacterium tuberculosis.* Abundant motion artifacts are noted.

Ground-glass change is increased pulmonary attenuation, with preservation of vascular markings (Figs. 10.52 and 10.53). This may be due to partial airspace filling or may represent dense intralobular septal thickening that is too subtle to be resolved due to the inherent resolution of the HRCT scanner. Thus, the concept of partial volume effect comes into play when HRCT images show hazy opacification resembling airspace opacification when the abnormality lies in the interstitium.

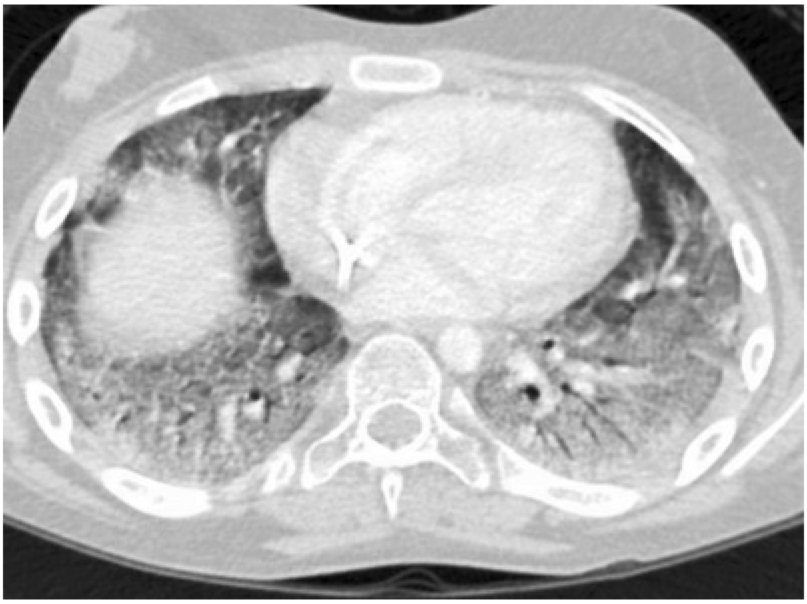

**FIG. 10.52** High-resolution computed tomography in a 4-year-old child undergoing chemotherapy shows widespread ground-glass change whose cause cannot be determined. However, in this setting, it is suggestive of drug-induced pneumonitis—in this case, probably bleomycin (see Fig. 10.21).

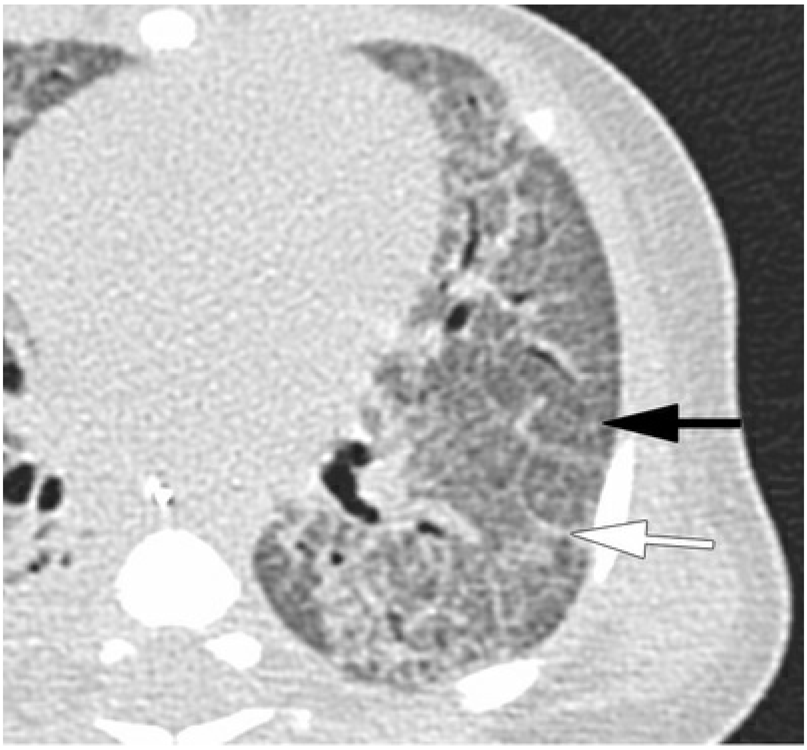

**FIG. 10.53** Detail from high-resolution computed tomography in a 3-month-old boy with neonatal onset of childhood interstitial lung disease (ChILD) shows homogeneous ground-glass change, interlobular septal thickening *(white arrow),* and discrete centrilobular nodules *(black arrow).*

Lung attenuation differs substantially between full inspiration and expiration. Diffuse, global ground-glass change may therefore be difficult to distinguish from a normal expiratory phase in the lungs. The posterior tracheal membrane is a helpful indicator because it is posteriorly convex on inspiration and horizontal or slightly anteriorly convex on expiration.

## Regional or Generalized Decreased Density

Circulating blood accounts for most of the normal parenchymal radiopacity. Consequently, decreased radiodensity is most commonly caused by abnormally reduced perfusion due to reflex vasoconstriction in small airway disease. This can be regional (mosaic attenuation) or global (Fig. 10.54).

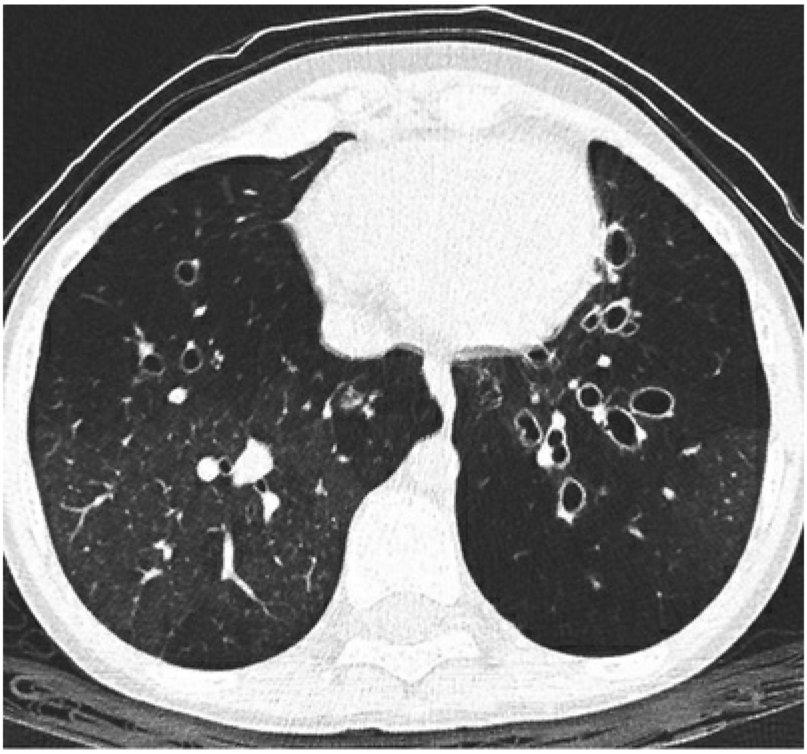

**FIG. 10.54** High-resolution computed tomography slice shows bronchial dilation with mild bronchial wall thickening (large airway disease), as well as almost globally hypoattenuating lung parenchyma and associated hypovascularity (small airway disease) in a 9-year-old boy with bronchiectasis.

Differentiation between mosaic attenuation and regional ground-glass change is often difficult. In this case, acquisition of expiratory scans to document air trapping associated with small airway disease can be useful (Figs. 10.55 and 10.56). As described above, in uncooperative children, if breathing cannot be controlled voluntarily (normally younger than 5 years of age), a few slices can be acquired in alternating decubitus positions. The dependent lung simulates expiration as the dependent hemithorax is splinted and its motion restricted, causing underaeration of the dependent lung and relative hyperaeration of the nondependent lung, effectively providing an expiratory view of the dependent lung and an inspiratory view of the nondependent lung.[22]

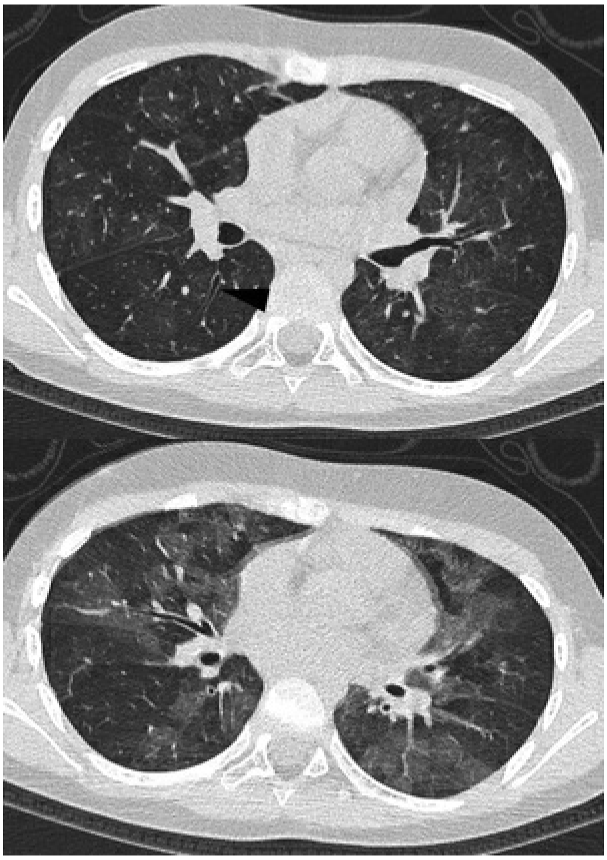

**FIG. 10.55** In an 11-year-old girl who received a bone marrow transplant, on inspiration *(top);* there are global attenuation differences seen in a mosaic pattern, as well as bronchial dilation *(arrowhead).* The mosaic pattern is accentuated on expiration *(bottom),* suggesting air trapping within low-attenuating segments.

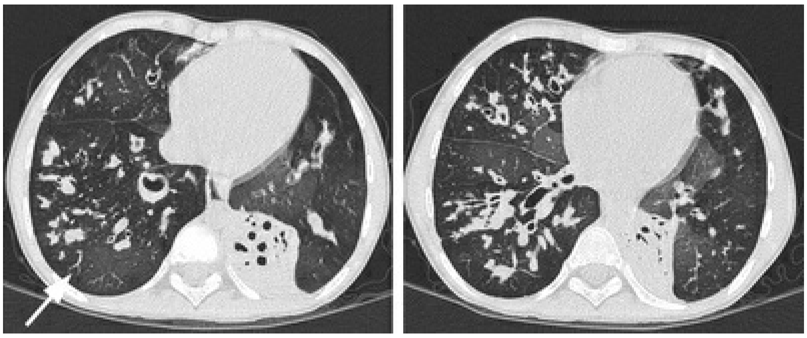

**FIG. 10.56** High-resolution computed tomography in an adolescent girl with end-stage cystic fibrosis shows mosaic attenuation, dilation, and wall thickening of the bronchi; mucus within the bronchi; and terminal branches with tree-in-bud sign *(arrow).* On expiration

*(right)*, there is accentuation of the mosaic pattern, confirming small airway obstruction.

This is useful in practice for the detection of air trapping in the dependent lung. In small airway disease, the contrast between underperfused and more normal tissue increases on expiration due to air trapping, enforcing the mosaic appearance.

## Septal Thickening

Intralobular interstitial thickening appears as fine weblike outlines, representing abnormal thickening of the lobular connective tissue or lobular bronchovascular interstitium due to inflammation or edema. If it is coarser, it resembles ground-glass change (discussed earlier).

Interlobular septal thickening is best appreciated in the subpleural lung, where it outlines the secondary pulmonary lobules. It may be the result of interstitial edema, hemorrhage, fibrosis, cellular infiltration, or lymphangiectasia (Fig. 10.57; see also Fig. 10.53). Diseases that affect the peripheral acini of two adjacent lobules may give the same appearance.

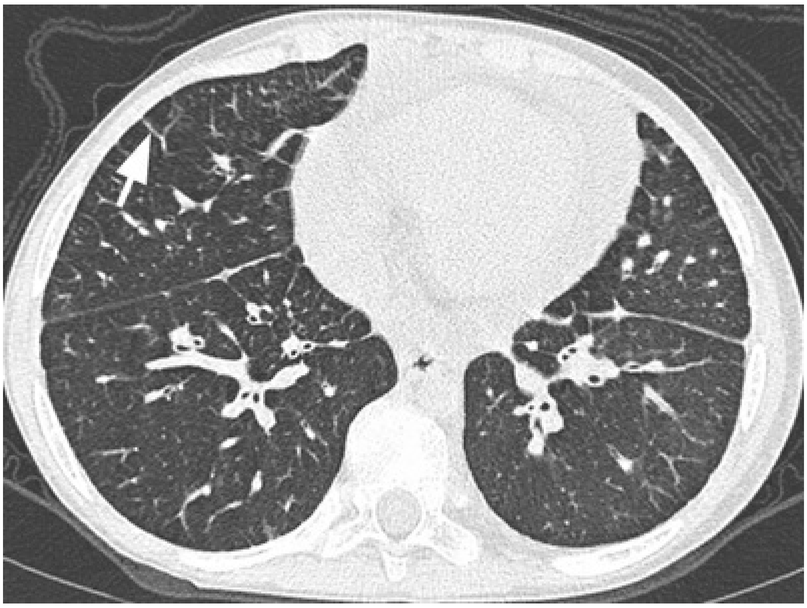

**FIG. 10.57** In a 13-year-old boy with known enteric lymphangiectasia, high-resolution computed tomography shows thickening of the oblique fissures, interlobular septal thickening *(arrow)*, and

peribronchovascular thickening. This suggests mild pulmonary involvement.

Peribronchovascular thickening is prominence of the bronchial walls or pulmonary arteries, usually with conspicuous centrilobular arteries. In the more extreme forms, this is caused by cellular infiltration (tends to appear nodular) or edema (smooth).

Interlobular septal thickening superimposed on ground-glass change is termed the *crazy paving pattern,* which is most commonly seen in childhood-type pulmonary alveolar proteinosis.

## Nodules

Random nodules are small infiltrates with no predominant anatomic association, typically seen in hematogenously spread disease (e.g., metastatic disease, miliary tuberculosis). Centrilobular nodules are nodular densities located centrally within secondary pulmonary lobules and are therefore equally spaced. They represent small infiltrates associated with bronchioles and alveolar ducts (e.g., infection, hypersensitivity pneumonitis). Centrilobular nodules (Fig. 10.58; see also Fig. 10.53) may coexist with peribronchial inflammation and impaction of fluid, cells, or mucus in the centrilobular bronchioles (see Fig. 10.56). The nodular branching patterns cause the characteristic tree-in-bud finding. This is a sign in infectious bronchitis/bronchiolitis, bronchiectasis, and tuberculosis. Perilymphatic nodules are small infiltrates associated with the visceral pleura, interlobular septa, and bronchovascular bundles (e.g., sarcoidosis).

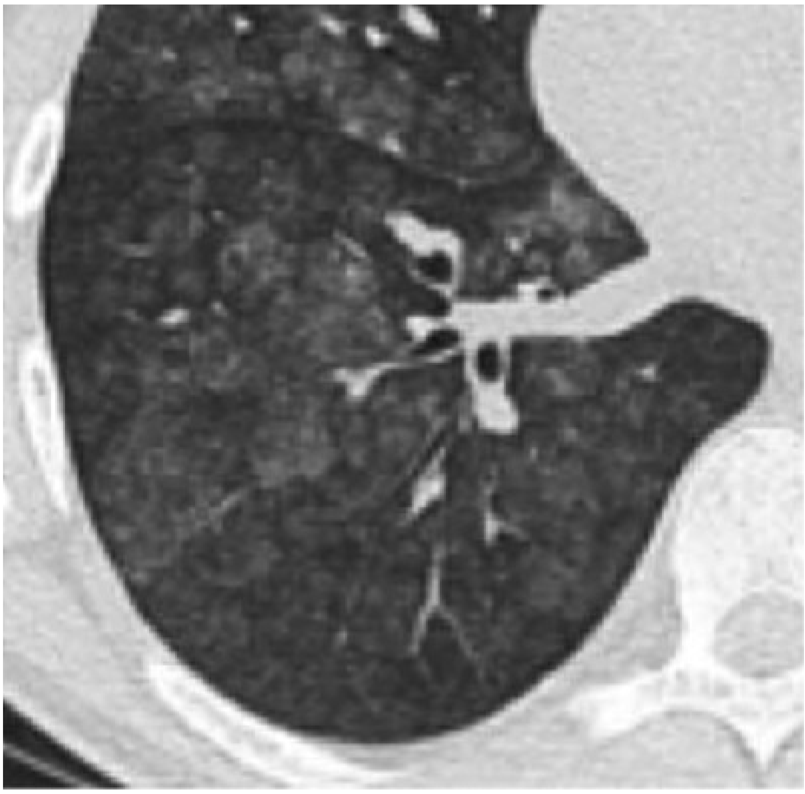

**FIG. 10.58** In a 12-year-old girl with anemia and intermittent hemoptysis, high-resolution computed tomography shows centrilobular ground-glass nodules suggestive of idiopathic pulmonary hemosiderosis.

## Bronchial Change

Bronchiectasis is dilation of the bronchus. The commonly used cutoff point for normal/abnormal equals the diameter of the adjacent artery. In early phases of cystic fibrosis, small airway disease represented by mosaic attenuation may be the only finding evident on HRCT. With advancing disease, the typical pattern is seen: bronchial dilation accompanied by bronchial wall thickening, mucus impaction, and architectural distortion (see Fig. 10.56). Bronchial dilation with minimal bronchial wall change and coexisting severe small airway disease usually points toward constrictive obliterative bronchiolitis (see Fig. 10.54). Bronchial wall thickening without dilation, often with patchy consolidation, is often seen in chronic aspiration (Fig. 10.59). It is sometimes difficult to distinguish between bronchial distention secondary to high ventilator pressure and genuine bronchial dilation. There is much controversy regarding reversibility of bronchiectasis, so serial imaging is the gold standard for irreversibility (i.e., fixed dilatation and wall thickening).

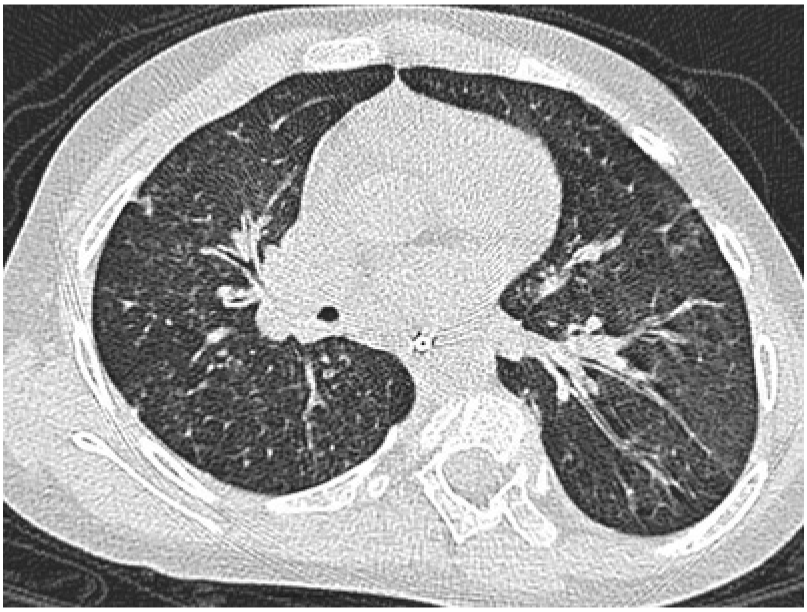

**FIG. 10.59** High-resolution computed tomography confirms bronchial wall thickening and shows small foci of subpleural interlobular septal thickening in a 9-year-old girl with gastroesophageal reflux and chronic aspiration (see Fig. 10.26).

A paper by Gaillard and colleagues[23] advised caution with diagnosing "bronchiectasis," as reversibility of radiologic findings can be seen in children. They suggest that serial imaging is required to confirm irreversibility before using the term *bronchiectasis* in children. They add that, as diagnostic criteria are derived from adult studies that have not been validated in children, cautious interpretation be made of CT findings. Their study included 22 children over a 6-year period, who had at least two lung CT scans, with a median scan interval of 21 months (range 2–43 months). Bronchial dilation resolved completely in 6 children, and there was improvement in another 8 patients. Hence, labeling children with an irreversible lifelong condition requires caution on the part of the radiologist.

## Architectural Distortion

Fibrosis and altered elasticity of the tissues permanently alters the structure of the lung parenchyma. This is seen as reduced parenchymal attenuation, cysts, deviation of vessels, bronchi and interlobular septa, and traction bronchiectasis (see Fig. 10.56). Cyst formation may also be caused by cystic resolution of pneumonia, forming a pneumatocele, or necrotic change of a preexisting parenchymal nodule (e.g., degeneration of granulomatous change in Langerhans cell histiocytosis, vasculitis, or granulomatosis with angiitis) (Fig. 10.60). Seen in end-stage disease, honeycombing is the result of clusters of thick-walled air cysts, representing structurally distorted, dilated respiratory bronchioles lined by fibrotic tissues, collapsed alveoli, and vessels.

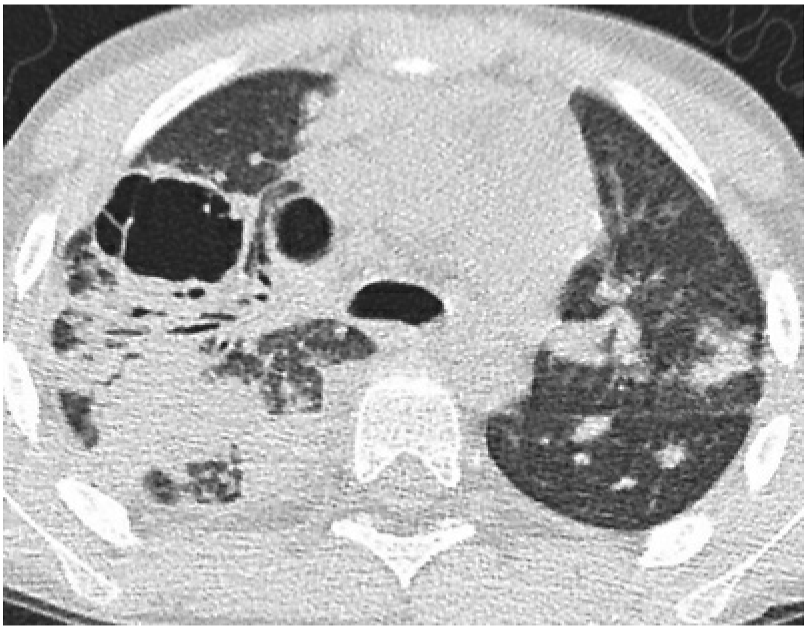

**FIG. 10.60** High-resolution computed tomography shows architectural distortion with large nodular change, air cyst, traction bronchiectasis, and pleural thickening in the right lung, and nodular change in the left. Histopathology verified nonspecific necrotizing vasculitis (see Fig. 10.20).

## Angiography

In noncardiac chest pathology, angiography is most commonly used for mediastinal vasculature and cystic congenital lung malformations. Magnetic resonance angiography is a useful noninvasive technique with no radiation burden.

Interventional techniques, such as embolization of bronchial arteries, are performed in cases of severe hemorrhage/hemoptysis in cystic fibrosis. Therapeutic embolization of feeding vessels to intralobar or extralobar sequestrations or to pulmonary arteriovenous malformations can be performed using metallic coils, thereby avoiding thoracotomy.

## Magnetic Resonance Imaging

Nonionizing radiation techniques should always be considered in pediatrics, and MRI is a highly desirable diagnostic tool for use in children, although drawbacks include the increased use of sedation or general anesthesia to accommodate the prolonged scan times and resultant susceptibility to movement artifact.

The multiplanar imaging capabilities of electrocardiogram-gated MRI and magnetic resonance angiography make these important methods for evaluating cardiac lesions; anomalies of the mediastinal vessels; and masses, such as bronchopulmonary foregut malformations, chest wall masses, bone marrow infiltrations, tracheobronchial abnormalities, and neurogenic masses (Fig. 10.61).

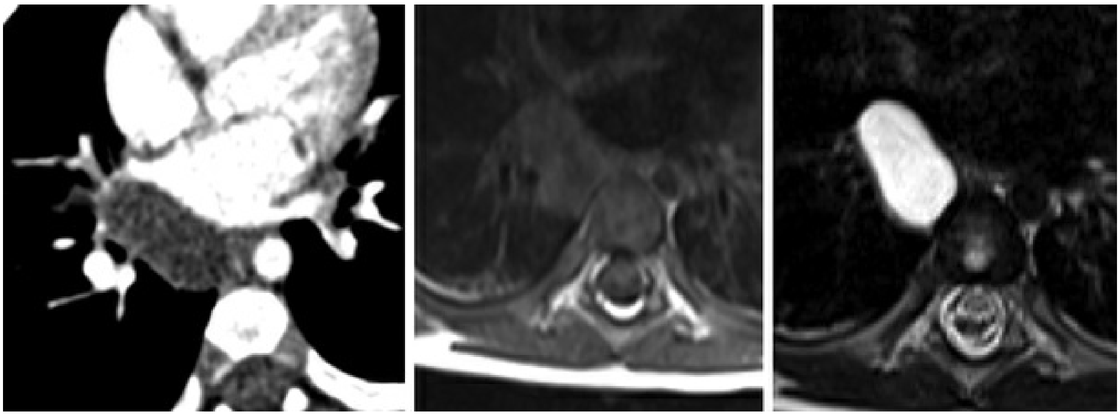

**FIG. 10.61** Axial computed tomography demonstrating a low attenuation lesion inferior to the right hilum. T1- and T2-weighted magnetic resonance imaging images demonstrating low T1 signal and high T2 signal in

keeping with fluid, further suggesting the diagnosis of mediastinal bronchogenic cyst.

The multiplanar capability of MRI, combined with its superb soft-tissue contrast resolution, allow for diagnosis that is more specific. Ongoing refinements, with improved gating techniques and shorter scan times, are under continuous development and continue to enhance the role of MRI in evaluating the pulmonary hila, lung parenchyma, heart, and diaphragm.

Although MRI is well established in cardiac imaging, experience with lung MRI is still limited. The main technical problems are: (1) low proton density in the lungs—hence a very weak signal return (echo) from the lung parenchyma; and (2) pulse and motion artifacts from the heart, great vessels, and respiration, causing significant image degradation.

MRI achieves tissue contrast first by adjusting the train of excitation, refocusing radiofrequency pulses, and switching magnetic field gradients. A T1-weighted MRI sequence takes advantage of the relatively fast realignment with the main magnetic field of fat molecules, so that fat appears bright on the acquired images. Such images are generally useful for studying anatomy. T2-weighted MRI sequences play on the relatively slow realignment of water molecules with the main magnetic field. Because water appears bright on these images, they are particularly helpful in detecting fluid collections and edema. These fundamental MRI techniques provide good depiction of structural pulmonary changes in cystic fibrosis.[24]

A second facility for creating image contrast, or enhancing inherent tissue imaging contrast, is the administration of intravenous MRI contrast medium, which is usually gadolinium chelate. This is typically combined with a T1-weighted pulse sequence and gives superb images of vascular structures, and potentially even the most peripheral vessels. Additionally, contrast media are useful for detecting vascular enhancement in inflammatory or neoplastic lesions (Figs. 10.62 and 10.63).

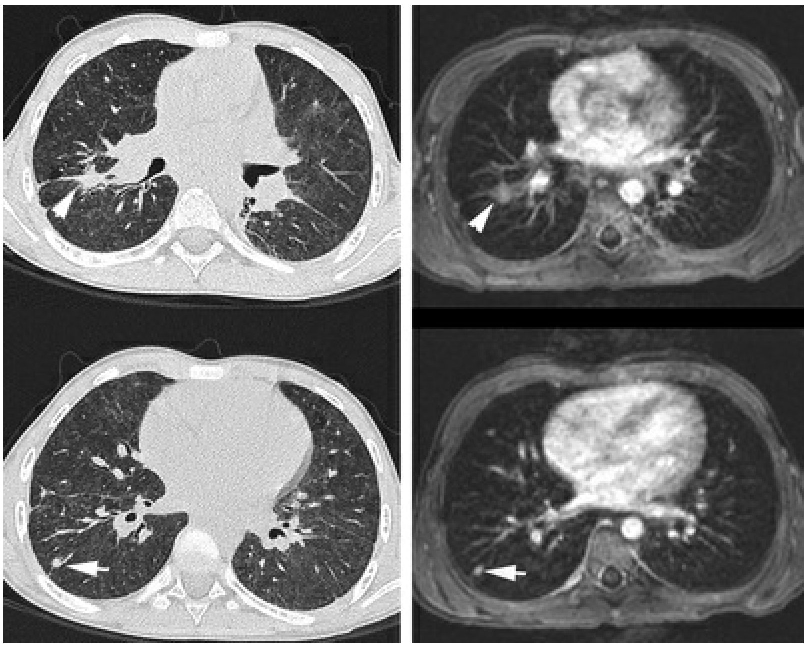

**FIG. 10.62** In a 12-year-old boy with chronic granulomatous disease, high-resolution computed tomography *(left)* and contrast-enhanced three-dimensional gradient echo magnetic resonance imaging *(right)* acquired on the same day, show corresponding findings of spiculated, enhancing lesions near the right hilum *(arrowheads)* and subpleurally in the right lower lobe *(arrows).*

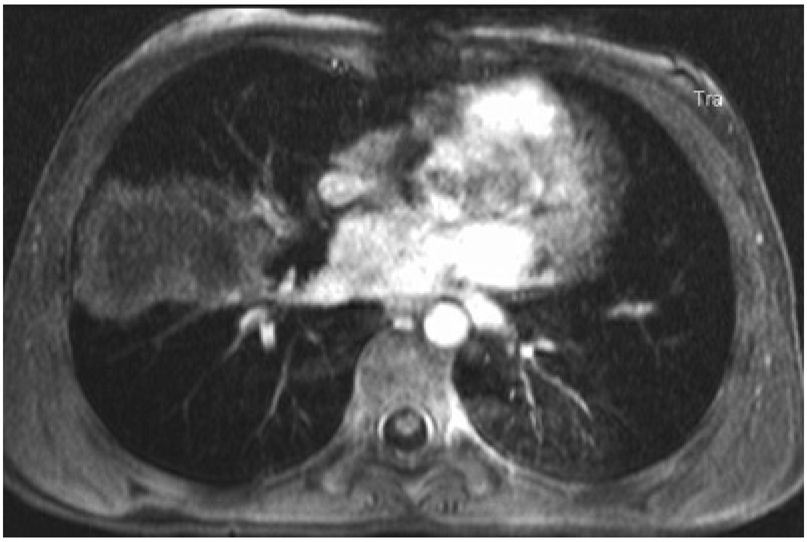

**FIG. 10.63** A 12-year-old boy who received a heart-lung transplant had a right-sided density on chest radiographs. Magnetic resonance imaging (T1-weighted gradient echo, breath-hold, gadolinium-

enhanced) shows an enhancing mass lesion in close relation to the right oblique fissure. Histopathologically, this was diagnosed as (posttransplant) lymphoproliferative disease.

Ultrafast pulse sequences with three-dimensional acquisition of volumetric MRI data are diagnostically promising and can be implemented on most modern scanners. Although the diagnostic accuracy is still largely unknown, MRI potentially may be used for imaging parenchymal lung lesions,[25] and high accuracy compared with CT has been demonstrated for nodules of 3 mm or larger in size.[26] Recent headway has been made utilizing respiratory-gated ultrashort echotime MRI sequences with radial reconstruction, allowing fast and quiet imaging with a spatial resolution far closer to that of CT than previously possible (0.86 $mm^3$).[27] While these techniques show promise in the setting of larger focal lung lesions and established bronchiectasis, particularly in cystic fibrosis, the spatial resolution is still not yet sufficient to replace CT in the context of more subtle disease, such as the mosaic attenuation demonstrated by CT in constrictive obliterative bronchiolitis and in early CF lung disease.

Currently, more promising MRI techniques offer functional measures of lung disease.

Breathing hyperpolarized helium allows the detection of a signal from within the airspaces, offering ventilation maps similar to those obtained via nuclear medicine studies. Unfortunately, the necessary equipment is expensive and the gas has a short half-life. As a result, this technique is not readily available in most imaging centers. Less expensive methods of gas imaging utilizing inhaled fluorinated gases or pure oxygen show great future clinical potential.[28]

Quantification of regional pulmonary perfusion is promising in the assessment of small airway disease. This can be achieved with time-resolved measurements, following an intravenous bolus of gadolinium. Although not widely used, the technique is available on most modern MRI systems, and there is good agreement with functional tests (Fig. 10.64).[29]

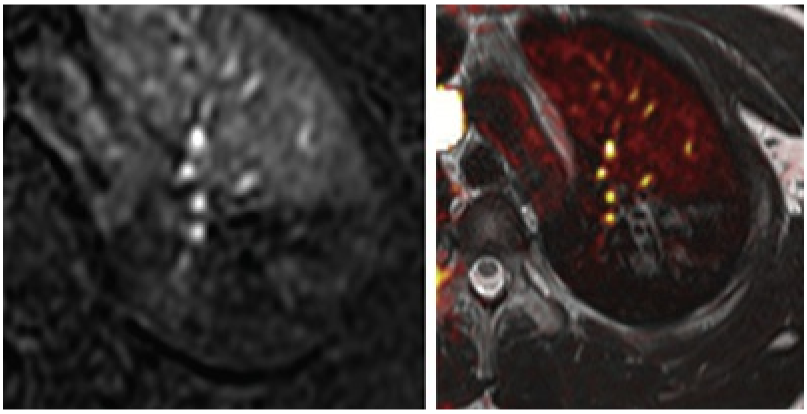

**FIG. 10.64** Subtraction perfusion image (fat suppressed T1 volume interpolated breath-hold examination [VIBE] precontrast subtracted from postcontrast) and fusion image (previous image superimposed in red over the T2 turbospin echo image to better demonstrate underlying anatomy) in a cystic fibrosis patient demonstrates thick-walled bronchi in the left upper lobe associated with a regional hypoperfusion.

A noncontrast technique—arterial spin labeling—is promising, judging by early feasibility studies.[30] Its potential advantage is that no injection is required and measurements may be repeated as necessary. A combined noncontrast ventilation/perfusion technique utilizing Fourier decomposition has also been described.[31] Roles for diffusion-weighted imaging in the assessment of inflammatory and neoplastic disease are also rapidly emerging.

# Endobronchial Ultrasonography

A paper published by Steinfort and colleagues[32] advocates that endobronchial ultrasound (EBUS) should be used in pediatric patients. The technique of endoscopic ultrasound has been used for the gastrointestinal tract for many years and has significantly advanced bronchoscopic techniques in adult respiratory medicine. In adults, the use of image guidance with ultrasound allows more accurate localization and sampling of peripheral pulmonary lesions, as well as mediastinal and hilar masses. This results in a greater diagnostic yield with reduced procedural complication rates in clinical practice, so it would appear that EBUS performance characteristics in adult populations are equivalent to surgical procedures that were previously considered the gold standard. Moreover, when compared to surgical approaches, there has been a dramatic reduction in morbidity and mortality among adult patients requiring invasive diagnostic procedures.

Steinfort and colleagues illustrate and advocate the various types of EBUS in clinical use, the methods of usage, and the clinical indications for each procedure, highlighting the potential role for EBUS in pediatric pulmonology.[32] Radial probe EBUS is used in the investigation of peripheral lung lesions (e.g., suspected invasive pulmonary aspergillosis) and could be adopted in children to achieve accurate biopsy of such lesions.

Linear probe EBUS allows a minimally invasive biopsy of mediastinal and hilar lesions. It has potentially greater performance characteristics than current biopsy techniques, with no significant complications reported to date. It may be useful in the diagnosis of lymphoma, or neurogenic tumors, and many other diseases resulting in mediastinal or hilar lymphadenopathy.

Certainly EBUS is a minimally invasive technique allowing tissue sampling of peripheral lung lesions, or mediastinal/hilar masses, with high diagnostic accuracy, and a significantly lower morbidity and mortality than alternative approaches. Hence, the indications for and the usage of EBUS in pediatric patients appear to be promising and will surely increase in the future.

Optical coherence tomography is a further promising bronchoscopic imaging technique allowing detailed imaging of the airway wall to a depth of 2–4 mm at a resolution of 1–15 µm. The technique involves the interpretation of back-scattered, near-infrared frequency light from a diode at the tip of an endobronchial probe, similar in principle to ultrasound, using light instead of sound. Additionally, rotation of the probe enables the formation of three-dimensional image data.[33] Numerous uses have been investigated in pulmonary medicine, including the investigation of tracheal stenosis and real-time dynamic evaluation of tracheobronchomalacia.[34]

## Ultrasonography

There has been controversy within the recent literature surrounding the possible uses of ultrasound within pediatric lung parenchyma. Ultrasound has a well-established role in the investigation of many thoracic diseases, in differentiating simple pleural effusion from complex (loculated, septated) empyema or densely consolidated peripheral lung parenchyma (Fig. 10.65) and its real-time dynamic imaging in assessment of differential organ motion, such as diaphragmatic and laryngeal movement in phrenic and recurrent laryngeal nerve palsies, respectively (Videos 10.7 and 10.8). Color flow Doppler imaging allows functional assessment of vascularity and can aid identification of systemic feeding vessels in pulmonary sequestration (Fig. 10.66). Suggested roles for ultrasound in noncardiac thoracic investigation can be found in Box 10.1. Further example images and videos can be found in the online supplement (Box 10.2).

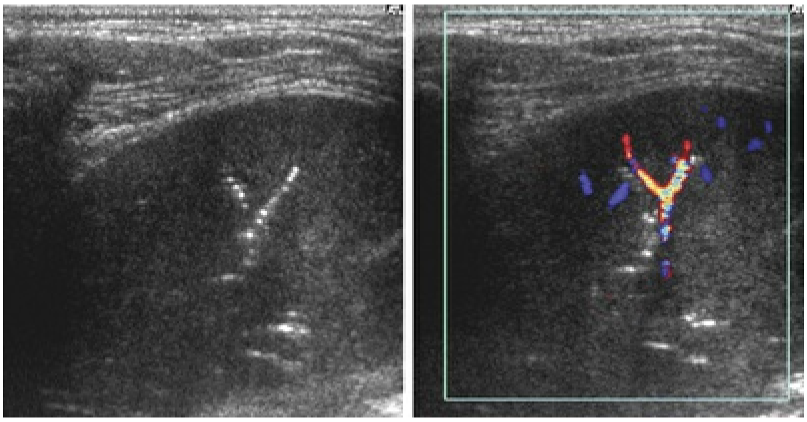

**FIG. 10.65** Ultrasound images of pulmonary consolidation. B mode image *(left)* demonstrating a bright air bronchogram in a densely consolidated lobe. Addition of color flow imaging *(right)* demonstrates flow in the adjacent accompanying pulmonary artery *(red)* demonstrating their relationship to the bronchial tree. Pulmonary venous *(blue)* branches are also shown.

## Suggested Roles for Ultrasound Within Pediatric Respiratory Medicine

**Peripheral increased opacification**—pleural effusion vs. consolidation (see Fig. 10.49 vs. Fig. 10.65)

**Pleural fluid**—simple effusion (transudate) vs. empyema or hemothorax (see Fig. 10.49)

### Chest Wall Lesions

**Widened mediastinum**—mass lesions, prominent thymus, etc.

**Thymus**—focal abnormalities, presence or absence; e.g., DiGeorge syndrome (see Fig. 10.1)

**Diaphragm**—phrenic nerve palsy, hernia, eventration (see Video 10.7)

**Larynx**—recurrent laryngeal nerve palsy (see Video 10.8)

**Sequestration**—presence of infradiaphragmatic systemic "feeding" vessel (see Fig. 10.66)

**To guide intervention**—aspiration, drainage, and biopsy (pleural, peripheral parenchymal, and mediastinal)

Fluoroscopic diaphragm assessment in phrenic nerve palsy (see Video 10.6)
Ultrasound assessment in phrenic nerve palsy (see Video 10.7)
Laryngeal ultrasound (see Video 10.8)
Ultrasound of the normal thymus (transverse section) (see Video 10.9)
Ultrasound of pulmonary consolidation (see Video 10.10)
Bronchogram in extrinsic airway compression (see Video 10.11)

### Cases

Bronchial atresia (see Video 10.12)
Constrictive obliterative bronchiolitis following mycoplasma pneumonia (see Video 10.13)

There are recent publications suggesting a role for ultrasound in the bedside assessment of the lung parenchyma, suggesting its use as a replacement for chest radiography. This has led to some confusion as various physical artifacts have been cited as implying the presence (or indeed absence) of intrathoracic lung parenchymal pathology. "A lines" refer to horizontal reflections of the lung edge resulting from an aerated subpleural lung. "B lines" refer to vertical bright lines resulting from ring-down artifact from isolated gas bubbles within extravascular fluid, suggesting pathology. However, these signs are not specific for a given pathology (Fig. 10.67).[35]

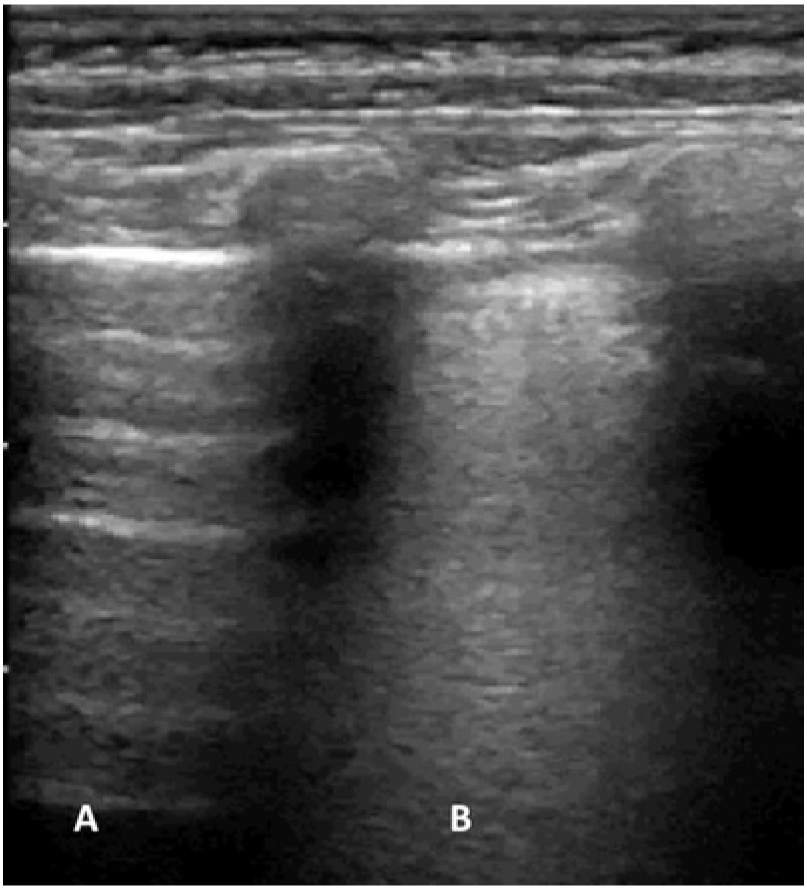

**FIG. 10.67** "A lines"—horizontal bright reflections of the pleural surface—indicate that the subpleural lung is aerated. "B lines"—vertical bright lines—"ring-down" artifact from isolated gas bubbles within extravascular fluid. (Image courtesy of P Tomà.)

The "lung point" sign—that is, the presence of a transition from darker, more transonic lung towards the apices to brighter lung inferiorly—has been associated with transient tachypnea of the newborn, with the suggestion that more nonresorbed fluid in the dependent lung causes an increase in "B lines" (Fig. 10.68). The lungs of premature neonates with idiopathic respiratory distress syndrome (iRDS) have been found to produce particularly bright B lines, which become coarser with the onset of more chronic lung disease (Fig. 10.69).

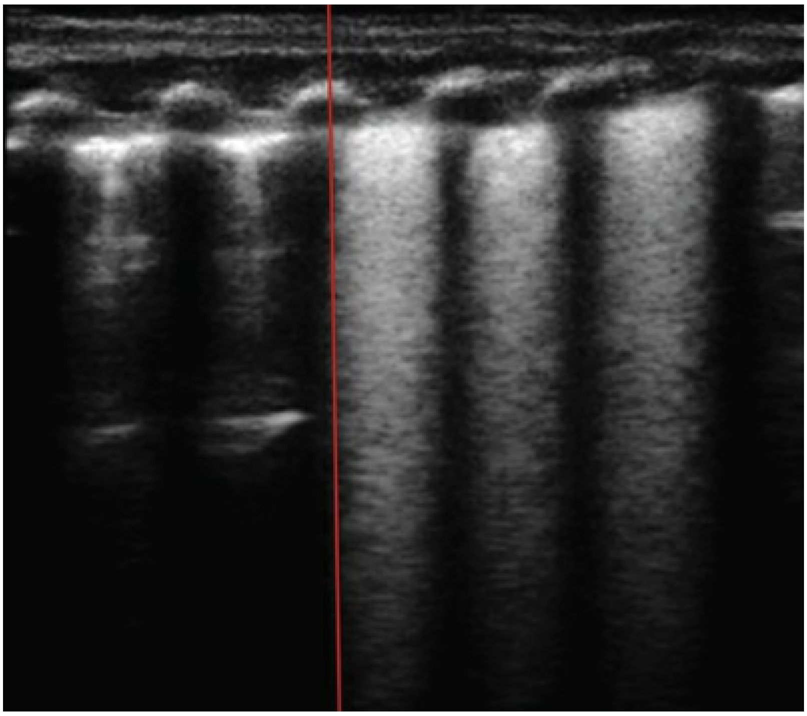

**FIG. 10.68** The "lung point" sign. The transition from darker apical lung (to the left of the *red line*) to brighter lung at the bases (to the right of the *red line*) is suggestive of transient tachypnea of the newborn (TTN). (Image courtesy of P Tomà.)

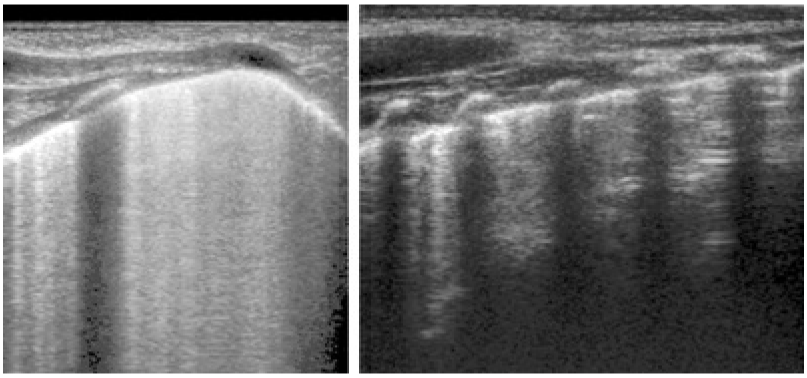

**FIG. 10.69** Ultrasound images of a premature neonate with idiopathic respiratory distress syndrome. At day 0,

bright B-lines are demonstrated *(left image)*. By day 5 *(right image)*, the appearance is more coarse and heterogeneous. (Image courtesy of P Tomà.)

While there is no doubt that ultrasound is capable of demonstrating pulmonary parenchymal disease, its significant limitations should be understood. While the above changes consistent with iRDS can be demonstrated, the diagnosis can be made clinically with no imaging at all, and ultrasound cannot adequately demonstrate the complications (particularly the clinically significant air leaks: pulmonary interstitial emphysema, pneumopericardium, etc.) and the positions of the numerous support tubes and lines that are so readily demonstrated via chest radiography. Peripheral pneumonic consolidation is readily identified, but more deep-seated infection, which does not subtend the pleural surface, will not be appreciated, and any related mediastinal lymphadenopathy will be overlooked. However, lung ultrasound has played a role in the research-based frequent follow-up of pneumonic consolidation in resource-poor areas, as utilized in the Drakenstein Child Heath Study.[36]

The chest radiograph remains the first modality of choice within pediatric chest imaging, with the other modalities reserved for further, more specific questions, directed by the preceding radiograph.

## Radionuclide Imaging

Nuclear medicine techniques are used to help delineate cardiac function, right-to-left pulmonary arteriovenous malformations, pulmonary embolism, inflammatory lung disease, and lung ventilation/perfusion (Fig. 10.70). While nuclear medicine has been the main tool for functional assessment of the heart and lung, the technique is gradually being replaced by CT for assessment of pulmonary embolism and small airway disease, and by MRI for combined assessment of cardiac morphology and function.

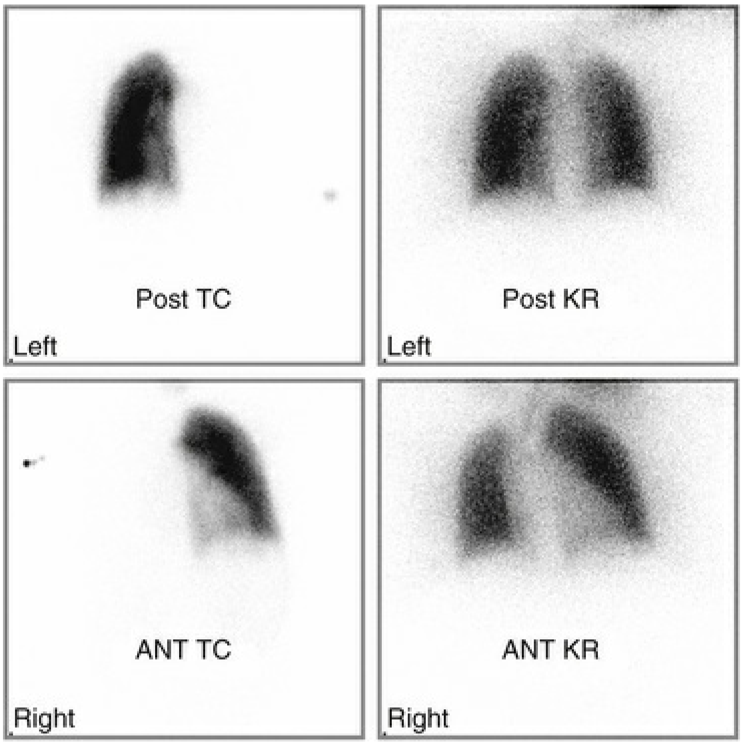

**FIG. 10.70** A ventilation/perfusion isotope study in a patient with absent right pulmonary artery on computed tomography confirms interrupted pulmonary arterial supply to the right lung *(left panel).* The hypoplastic right lung has preserved ventilation (*right panel;* see Figs. 10.4 and 10.45). *KR,* Inhaled krypton ventilation images; *TC,* intravenous 99m technetium microaggregated albumin (MAA) perfusion images.

Positron emission tomography (PET) is a promising modality. It uses biologically interesting radionuclides (e.g., fluorine 18, carbon 11, oxygen 15, nitrogen 13) to mark biochemical substrates (e.g., glucose). PET is therefore a modality for metabolic rather than structural studies, and in patients with malignant disease, PET uses the relatively high glucose metabolism in malignant cells for imaging. Combined with CT, or more recently MRI, anatomic and functional data can be fused into one image. The clinical efficacy of the technique is being explored, but the modality shows particular strength in oncologic imaging, both at diagnosis and in the follow-up of metabolic response to treatment.

# Conclusion

The approaches to radiologic evaluation of the child cannot be extrapolated from adult imaging. Particular awareness of the issues of radiation protection, anatomy and physiology, and the range of pediatric disorders is crucial. As with every test, the key is first to pose a focused question and then to select the best way of answering it, usually in consultation with expert colleagues. In general, chest radiography gives the first overall assessment of the presence or absence of disease, with the other modalities used to provide further more detailed information: CT for fine detail of the lung parenchyma; ultrasound for the definition of pleural pathology; and, more recently, MRI for functional information and more gross structural disease.

# Pulmonary Function Tests in Infants and Children

*Dorottya Czovek MD, PhD*

## Introduction

The childhood years represent a very important period of lung growth and development, during which the respiratory system is exceptionally vulnerable to any insult. Measuring lung function in infants and young children presents significant and particular challenges. An ideal lung function test for clinical use should: (1) be easy and quick to perform for both the children and testers even in a busy outpatient setting; (2) have standard operating procedures, guidelines and robust healthy reference data available; (3) discriminate between healthy children and those with respiratory disease with high specificity and sensitivity; (4) be feasible at any age for longitudinal follow-up of individuals with lung disease; and (5) be cheap and widely available to fulfill health care equality.

While the indications, methodology, and interpretation of lung function testing in children above 6 years of age is similar to those in adults, infants and preschool-age children require special technical and safety considerations (these will be discussed below). However, staff with a special attitude, understanding, patience, and love for the children are essential: child-friendly personnel is one of the main determinants of the success of any lung function test in young children.

## Indications and Special Considerations for Pulmonary Function Tests in Infants

Lung function can be measured as early as in the first days of life in infants for both clinical and research purposes. Correctly performed lung function tests during infancy can provide information on lung growth and development, disease status, and progression, and can aid the clinicians in decision making. Most of the lung function tests were originally developed for adults and later modified for the special requirements of infants and young children (e.g., plethysmography and multiple breath washout [MBW]), while others have been designed specifically for infant testing (e.g., single occlusion technique [SOT]). Although commercial devices and validated guidelines are often available, infant lung function testing is not always part of the routine practice of pediatric respiratory laboratories. This is most probably due to the special technical and personal requirements that are essential for successful lung function testing during infancy.

### Technical and Staff Requirements

Since all of the lung function tests are performed during quiet sleep or sedation, the appropriate location of the infant testing room is very important for the success of the test. In laboratories where lung function testing is performed routinely as part of the clinical care, the infant study room should be isolated from those for preschool- and school-age children. The room containing the lung function devices and consumables has to be comfortable and large enough to accommodate two examiners, one or two parents (and sometimes siblings), and equipped with everything that is necessary for changing and settling the infant.

Since the visit can take as long as 3 or 4 hours, the procedures and their duration (either clinical or research study visit) should be discussed in detail with the parents prior to the appointment. It is important to consider that many of the mothers may be still breastfeeding at the time of the measurement; therefore privacy has to be provided to the parents, if necessary.

Resuscitation equipment has to be available in the room and, for safety and technical reasons, two skilled examiners have to be present at the time of the testing. If the test is performed during sedation (see later) heart rate and oxygen saturation should be monitored continuously.

Infant lung function testing is technically challenging; therefore the examiners have to be properly trained. They should be able to recognize any technical problems (such as software problems, leak in the system during the test), and it is desirable that they have a basic understanding of respiratory physiology. Since the test is time consuming, there is usually no opportunity to repeat it (especially when performed for research); therefore the real-time quality control (i.e., whether the test fulfills all quality criteria) and interpretation (i.e., whether the results are physiologically meaningful) of the test are crucial.

The infant lung function devices vary in their size and the consumables required. Since the tidal flow and volume during infancy are relatively small, maximum reduction of the dead space is a very important requirement in all lung function equipment. To avoid rebreathing of $CO_2$, most of the devices employ a bias flow (usually with medical air, but sometimes with oxygen or special gas mixtures).

In spontaneously breathing infants, all of the lung function tests are done through a facemask in the supine position (Fig. 11.1), which introduces the most common source of error in infant testing: the leak around the mask. Any leak invalidates all infant lung function tests; therefore the size of the facemask always has to be selected carefully and its position checked before and throughout the test. Furthermore, the facemask increases the equipment dead space, and its volume should always be taken into account for corrections. However, mask volume correction is not straightforward as one cannot always predict how much of the mask is occupied by the infant's face, raising the possibility of overcorrection for mask volume. Unsedated babies sometimes do not tolerate the facemask and wake up every time when the mask is positioned on their face; this is less frequent under sedation.

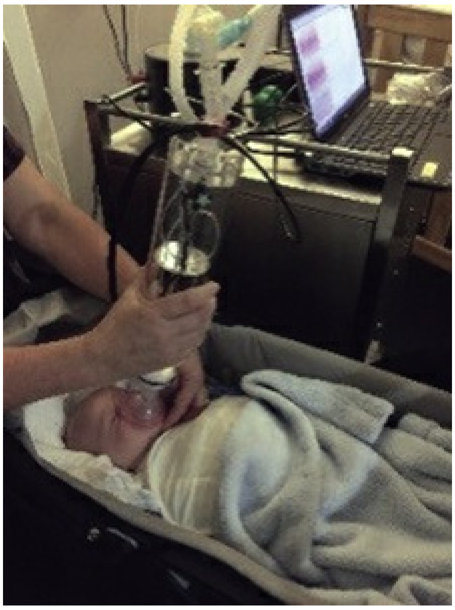

**FIG. 11.1** Infant lung function test using the forced oscillation technique.

In unsedated infants, the natural variability of the breathing pattern is significant, especially during rapid eye movement (REM) sleep. Previous studies have shown that during REM sleep breathing frequency is increased[1] and functional residual capacity (FRC) is unstable; therefore if the lung function test is undertaken without sedation, lung function should be measured during deep, non-REM sleep (whenever possible). Non-REM sleep can be recognized by observation of the baby, and a pulse oximeter can sometimes help to detect stable, regular heart rate (as heart rate is usually irregular and fast during REM sleep). Note: monitoring of oxygen saturation is mandatory when infants are sedated for lung function testing and optional for studies conducted during natural sleep. The sleep of preterm babies and neonates is usually superficial, and it is not always possible to differentiate between REM and non-REM sleep phases. Therefore a lung function test in preterm infants and newborns cannot always be undertaken in one sitting and sometimes requires two or three sessions. If more than one lung function test is performed in an infant, the tests that require tidal breathing should be undertaken first while the tests that require a controlled maneuver and may affect the respiratory status (e.g., rapid thoracoabdominal compression [RTC]) should be performed at the end of the visit.

Notes on the time and duration of the tests, and replacement of the facemask between measurements should always be recorded as well as the behavior of the infant (i.e., expiratory noise, snoring, sighs). These comments are useful for the correct interpretation of any infant lung function test.

## Lung Function Test in Sedated Infants

Although some lung function tests (typically the ones that require quiet tidal breathing) can be performed in unsedated babies sometimes as late as 1 year of age,[2] there are tests that are difficult or impossible to perform without sedation. Sedation for lung function testing has become less common and has to be considered carefully for either clinical or research purposes. If lung function is measured as part of the clinical care in an infant with ongoing respiratory problems, sedation is more accepted and tolerated by the parents. Collection of reference data in healthy infants can therefore be challenging, although it is required for the meaningful interpretation of any lung function measure in children with respiratory disease. Nowadays, many human research ethics committees hesitate to approve the sedation of healthy children or even children with respiratory disease for research purposes. Sedation is also contraindicated in neonates and preterm babies with immature respiratory control or any disorders that affect the neural system of the infant. Sedation affects the breathing pattern and the FRC of the infants; therefore data collected in unsedated and sedated babies with the same technique cannot be compared directly. However, it has been shown that the sedation has no effect on the activation of the Hering-Breuer reflex[3]; therefore it can be used safely in techniques such as the SOT or the low-frequency forced oscillation technique (LFOT).

Independently of the purpose of the sedation (i.e., clinical or research test), the exact process and the possible side effects always have to be discussed in details with the parents. It is important to note that even in sedated babies it can take from 15 to 90 minutes to reach quiet sleep that is necessary for the test. Chloral hydrate in an oral dose of 50–100 mg/kg is most frequently used for sedation and usually allows 30–45 minutes for the examiner to perform the lung function test(s). Side effects are extremely rare; however, parents always have to be provided with a phone number to call if they have any concerns after the visit, and they should also be advised not to leave the child unattended during the first few hours.

## Indications and Special Considerations for Pulmonary Function Tests in Children

Children older than 2 years of age cannot be sedated for a lung function test; however, their cooperation during the preschool years is limited: they are rarely able to perform complex respiratory maneuvers that are required for lung function tests routinely used in older children and adults. Furthermore, the anatomical and physiological differences in the respiratory system between young children and adults make the interpretation of lung function measures originally developed in adults less straightforward and sometimes meaningless. Common interests of clinicians and researchers have resulted in the development of novel lung function methods and modifications of previously available techniques; therefore nowadays more than half of the children at 3 years of age and 80% of the children between 4 and 6 years of age are able to perform acceptable lung function tests. Similar to adults, spirometry is the most frequently used lung function test in children above 6 years of age, while tests that only require tidal breathing are more favorable in preschool-age children.

### Technical and Staff Requirements

A child-friendly environment (Fig. 11.2) with engaged and friendly respiratory technicians or researchers is one of the most important key points for successful lung function testing in preschool-age children. Since children have a short attention span, their engagement throughout the test is crucial and sometimes challenging. The examiner should understand and respect the personality (and the current mood) of the child and should recognize which children will be able to (or will not be able to) perform the lung function test after some encouragement (if the child does not even want to stand on the scale, it is usually a bad sign). In a clinical setting, especially in children with chronic respiratory disease, attempts should always be made to perform the appropriate lung function test(s) even if the failure is predictable.

This will make the child comfortable and familiar with the test and can be considered as training for the next occasion. Giving the mouthpiece and nose clip to the child to play with at home can be a useful introduction and may increase testing success on the next visit.

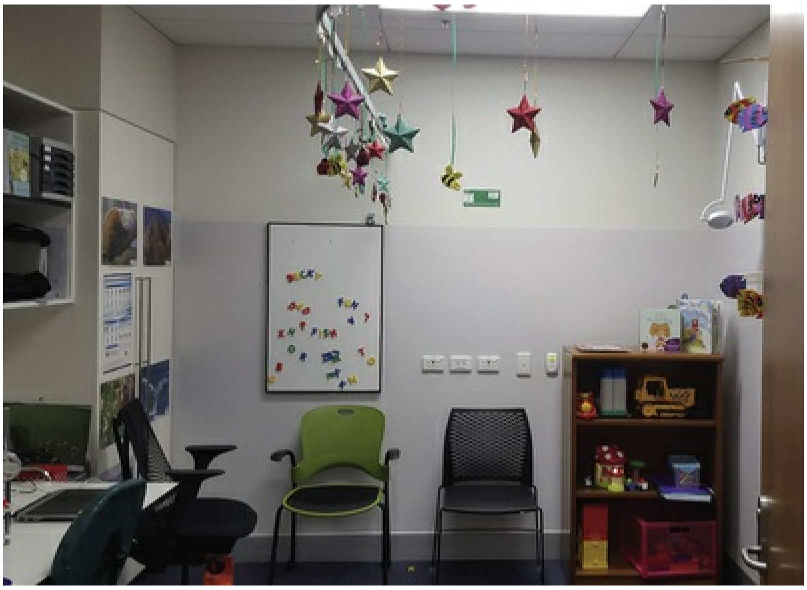

**FIG. 11.2** Lung function testing room designed for preschool-aged children. (Child Health Research Centre, Brisbane, Australia.)

It is always important to take the time and explain the test to the child in understandable language and even involve them in the preparation of the test (e.g., to connect the mouthpiece to the device). Young children can cope with the test better if it is separated into small steps and they have to complete one step at a time. Continuous positive feedback is very important and all the attention of the examiner should be focused on the child throughout the visit. For safety reasons, children should never be left unattended in the respiratory laboratory. Preschool-aged children are very open-minded and creative, they are always ready for some play and magic; therefore (if the examiner is prepared) the visit can be great fun.

Since clinicians are rarely present during the lung function test, technicians should provide them with written or verbal comments on the test when the results are presented. Comments on effort (in spirometry), posture, leak, etc., should always be recorded and taken into account for the interpretation. Bronchoprovocation tests are hardly ever done in children younger than 5 years of age; however, the response to bronchodilator is frequently assessed in both clinical and research settings. The bronchodilator test, its interpretation, and clinical utility will be discussed as a part of the detailed description of the lung function methods later in this chapter (see *Measurements of Forced Expiration* and *Measurements of Respiratory Resistance and Compliance*). Bronchoprovocation tests in children above 5 years of age are discussed in detail in Chapter 12 and therefore will not be included in this chapter.

As a part of the lung function test, information that is expected to influence the interpretation of the lung function results should always be collected, including date of birth, height, weight, sex, environmental data, and relevant medical and family history. The interpretation of the lung function data in adolescents is further complicated by the hormonal changes and their effects on lung growth. Healthy reference values, appropriate for both the measured population and the lung function device, therefore need to be selected carefully. Ideally, the results are presented in terms of *z-scores,* which take into account both the measured and predicted values as well as the test variability within the population. Reference values collected in multicenter studies are especially useful as they can prove the robustness of the technique in different research and clinical environments. The examiner always needs to investigate the relevance of the reference data and the results should be reported accordingly.

Manufacturers and local distributors should be aware of any specific requirements that are necessary for the clinical testing of infants and young children (i.e., dead space reduction, appropriate calibration device, facemask and filter, etc.) and always provide the users with in-depth training and relevant guidelines. This is especially important when a novel lung function method is introduced for clinical use to respiratory technicians and physicians who are not familiar with the requirements of the test and interpretation of data. The proper introduction of a novel method requires a high level of flexibility from the manufacturer and strong collaboration between researchers and clinicians to ensure the collection of reliable data and meaningful interpretation of the results in a clinical situation.

# Measurement of Lung Volumes

## Summary

- The measurement of lung volumes is crucial for the interpretation of lung function
- Functional residual capacity is the only lung volume that can be measured at any age
- Vital capacity and its subdivisions can only be measured in cooperative children with spirometry
- Total lung capacity and residual volume can be determined from the spirometric measures if FRC is known

The measurement of lung volumes in infants and children is crucial for the interpretation of the measures of lung mechanics (resistance and compliance), respiratory flows, and ventilation inhomogeneity, and can provide information on lung growth and development. There are two techniques that were originally developed for adults and later modified for infants and young children: *body plethysmography* and the *gas dilution technique.* While in cooperative, older children, a wide range of lung volumes can be determined, infants are not able, and preschool-age children have limited ability to perform complex respiratory maneuvers, therefore, only FRC (the volume of the gas present in the lungs at the end of a tidal expiration) can be determined reliably in the early years of life. The underlying assumptions of the measurement of FRC with plethysmography ($FRC_p$) or gas dilution technique ($FRC_g$) are different and therefore they require different devices and techniques; both methods have advantages and limitations over the other. Plethysmography estimates all gas compartments in the lungs irrespectively of whether or not they communicate with the airway opening, whereas in the gas dilution measurements only the communicating compartments are measured. In healthy individuals, the difference between $FRC_p$ and $FRC_g$ is minimal; however, this can be significant in the presence of air trapping when $FRC_g$ can be underestimated. In the recent years, measurement of $FRC_g$ with the MBW technique has become popular as it does not require sedation during infancy and it is more feasible in young children than plethysmography.

## Whole Body Plethysmography

### Summary

- Measurement of thoracic gas volume (including nonventilating areas)
- Commercial devices are available for both infants and children
- Mainly used in infants and cooperative older children as preschool-age children rarely tolerate the measurement
- Results are unreliable in the presence of severe airway obstruction (FRC is overestimated)
- Has become less common in infants and preschool-age children with the commercialization of MBW
- Frequently used in children above 6 years of age

The plethysmographic measurement of thoracic gas volume was first described in 1956 by DuBois and his colleagues[4]; however, the idea of performing respiratory efforts against a closed airway to measure lung volumes has been known since 1882.[5] Unlike the gas dilution technique, plethysmography measures the total thoracic gas volume, including the air that is not communicating directly with the airway opening. Commercial devices with normative values are available; therefore plethysmography has been used in both clinical and research environments during infancy.[6–8] Since sedation is usually required for the test in younger children, plethysmographic measurement of FRC has become less frequent in pediatric lung function laboratories. Despite the few studies that reported $FRC_p$ in preschool-age children,[9] its use is highly limited below 6 years of age and no robust reference data are available for young children. In research studies, reference values calculated for school-age children have been extrapolated to those between 3 and 6 years of age; this method does not meet criteria for predicting lung function in preschool-age children and cannot be used in clinical practice.

## Physiological Principles and Assumptions

The measurement of $FRC_p$ is based on Boyle's law, which describes the relationship between volume and pressure of a given amount of gas within a closed system, that is, in the thorax. The assumption is that if the temperature is constant within the system (isothermal conditions) the compression/decompression of the gas (decrease/increase in volume) will change the pressure, so that the product of pressure (P) and volume (V) is constant *(k)* at any moment:

$$PV = k$$

During an (inspiratory) breathing effort against a closed airway, the changes in P from $P_1$ to $P_2$ ($\Delta P$) can be measured, and the simultaneous expansion of the intrathoracic gas ($\Delta V = V_2 - V_1$) results in an opposite change in the gas volume in the plethysmograph box ($V_{box}$), that is,

$$\Delta V_{box} = -\Delta V$$

Thus, knowing $\Delta V$ and from the relative changes in alveolar pressure as measured by $P_1$ at the airway opening, preocclusion lung volume $V_1$ can be calculated as

$$V_1 = -P_1(\Delta V/\Delta P)$$

$\Delta V$ can be measured in the body box in which the subject is enclosed, in different ways: (1) as a volume displacement sensed by a closed-circuit spirometer (volume displacement plethysmograph), (2) via the pressure changes in the closed box (pressure plethysmograph), and (3) by integration of the flow across the box wall (flow plethysmograph).[10] This latter type including correction for the residual pressure in the box (pressure corrected flow plethysmograph) is the most commonly used equipment for measurement of intrathoracic gas volume.

In the actual measurement of thoracic gas volume, the patient is seated (or the infant placed, Fig. 11.3) in a tightly closed chamber where the changes in the mouth pressure and volume of the chamber are measured over different conditions. At the beginning of the test, tidal breathing is recorded. At this time, the volume of the gas in the chest is unknown while the alveolar pressure is equal to the atmospheric pressure when there is no airflow (i.e., end of expiration or inspiration). Once the end-expiratory level (EEL) is stable, the airways are occluded with a shutter and the patient generates respiratory efforts against a closed airway. In this new condition, mouth pressure is expected to equilibrate quickly with alveolar pressure (this equilibrium can be delayed in lung heterogeneity[11–13]; see also below concerning the limitations of the technique). From the pressure changes at the mouth and the changes in the volume of the airtight chamber, intrathoracic gas volume can be calculated, as described above. In infants, it is best to occlude the airways at the end of inspiration as it is less uncomfortable and more tolerable for the infant. If the occlusion appears at end inspiration, tidal volume ($V_T$) has to be extracted from the total gas volume when $FRC_p$ is calculated.[14]

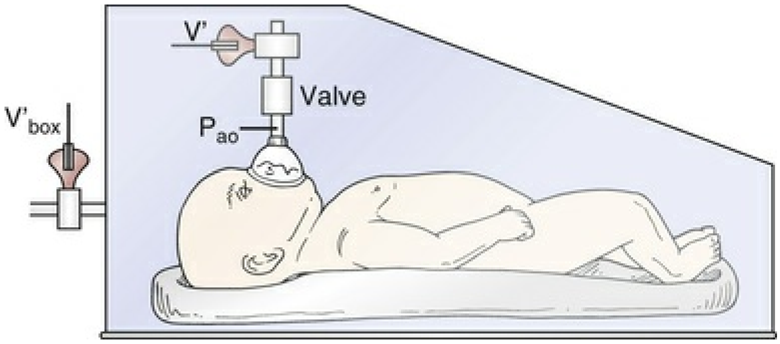

**FIG. 11.3** Schematic arrangement of the infant plethysmograph designed for the measurements of functional residual capacity (FRC) and specific airway resistance ($sR_{aw}$). Flows $V'$ and $V'_{box}$ are measured with pneumotachographs at the airway opening and through the plethysmograph box wall, respectively, for the estimation of $sR_{aw}$. The valve is closed against breathing efforts during the measurement of FRC.

Since the volume of the plethysmograph is relatively large in children and adults, they are asked to pant during the test with a frequency of approximately 60 breaths/min (1 Hz). This controlled breathing frequency helps the equilibrium of the alveolar and mouth pressures, keeps the glottic aperture open, minimizes the thermal drift, and so improves the quality of the test.[10] However, it is important to note that panting does not reflect the normal conditions within the respiratory system during tidal breathing. In infants, the volume of the chamber can be kept relatively small; therefore tidal breathing is adequate to ensure the quality of the test.

The feasibility of the test in infants depends on the sleep state (usually under sedation) and the stability of the EEL.[6] In preschool-aged children, the feasibility is limited as they do not tolerate the closed chamber and panting against a closed airway. In the studies where $FRC_p$ was measured in children between 3 and 7 years of age, the measurements were preceded by a long training session both outside and inside of the chamber (i.e., breathing through the mouthpiece and then mouthpiece occluded, supporting their cheeks, etc.). With this method, the test was successful in nearly 70% of the children.[9] In older children, the success rate is similar to that in adults.

## Quality Control, Acceptability Criteria, and Limitations

The installation of the equipment has to be planned carefully as both the infant and child plethysmographs are bulky and not portable. For infants, extra room for the adjustment of the facemask and rapid access to the infant has to be allowed for.

Even if the test appears successful, many factors can influence the quality of the measurement and the interpretation of the results. All plethysmographs require precise calibration on the day of the test, which can be time-consuming. Accuracy also has to be checked at least monthly (usually with a lung model or biological control). Prior to the test, the equipment has to be turned on to allow a sufficient warm-up period. The calibration procedure is equipment-dependent; therefore, the instructions of the manufacturer have to be followed step by step. Once the patient is comfortable inside the plethysmograph, the door is closed for a few minutes to stabilize the thermal conditions. Both the calibration and patient preparation (sedation in infants, training in preschool-age children) are time consuming and require patience from both the technicians and parents (and children). If the time allowed for thermal adjustment is not long enough the measurement is unreliable. In modern plethysmographs, the time that the patient has to spend in the chamber before the test is significantly shorter and this may help to make the test more feasible in young children.

Every occlusion should cover at least two complete respiratory efforts (6–10 seconds) and should be repeated three to five times during the test. $FRC_p$ is calculated as the mean (SD) of at least three technically acceptable recordings.

The time required for the equilibrium between the pressures at the airway opening and the alveolar system is highly influenced by the resistance and compliance of the upper airways. Usually, a firm support of the cheeks of the patient with the palms is sufficient to decrease the compliance of the cheeks and adequately measure FRC. In the presence of a severe obstruction, transmission of changes in the alveolar pressure may become too slow to reach equilibrium. In this case the change in airway-opening pressure, $\Delta P$ will underestimate the change in alveolar pressure and hence FRC will be overestimated.[12] Since infants are preferential nasal breathers, cheek support is not required for the test; however, after the placement of the facemask the system always has to be checked for leaks.

The steps necessary to ensure the quality of the test are equipment dependent and include high-quality pressure transducers and linear pneumotachographs (in the flow plethysmograph), carefully performed calibration, the measurement of biological controls, sufficient warm-up times, and correction of thermal drift. The general recommendations for standardization of the technique have been published, and specific recommendations for infant measurements are also available (see *Suggested Reading*).

## Spirometric Measurements of Lung Volumes in Cooperative Children

Once FRC is known, other physiologically and clinically important lung volumes can be measured with a simple spirometer and TLC and RV calculated (Fig. 11.4). The complex respiratory maneuver starts with tidal breathing wearing a noseclip. After a few breaths, the child is instructed to take a deep breath to the maximum inspiratory level and perform a maximum expiration thereafter, and finish with tidal breathing. The volume between the maximal inspiratory and expiratory levels is called vital capacity (VC). Following a maximal expiration there is always an air volume in the lungs that cannot be actively exhaled; this is called the residual volume (RV). TLC is therefore the air volume that the lungs contain at maximum inspiration, i.e., VC+RV. TLC and its subdivisions and their definitions are shown in Fig. 11.4. FRC, TLC, and RV have clinical relevance and therefore they are the most frequently reported lung volumes in older children and adults.

## Gas Dilution Technique

### Summary

- Measurement of $FRC_g$ with closed-circuit Helium dilution or MBW technique
- $FRC_g$ only represents the ventilated lung parts that are in communication with the airway
- This test is more popular than plethysmography as it is relatively easy to perform in unsedated infants and preschool-age children
- It is less commonly used in children above 6 years of age who are able to cooperate with the plethysmographic and spirometric measurements of lung volumes
- Commercial devices are available for both infants and children

- Main limitation is the underestimation of FRC in severe airway obstruction

The measurement of FRC with the gas dilution technique has been employed widely in infants and young children as it only requires tidal breathing. Until recently, closed-circuit helium (He) dilution was the most frequently performed test, while nowadays (since commercial devices for MBW test have been introduced), MBW has become more popular in both infants and preschool-aged children.

## Physiological Principles and Assumptions

The use of He to determine lung volumes was first introduced in 1941.[15] Since then, the gas analyzer systems have improved significantly; however, the concept of the test and the method of the measurement have remained nearly unchanged.[10] The basic assumption of the method is that the patient with an unknown lung volume breathes from a reservoir of known volume containing He in a known concentration (usually is around 15%). If the circuit is closed, lung volume equilibrates with He (as indicated by less than 0.02% fluctuation in the He concentration for at least 15 seconds) resulting in a decrease in the He concentration (Fig. 11.5). Since He does not transfer through the alveolar membrane to and from the circulation, the final amount of the He is the same as the initial amount (but distributed in a higher volume):

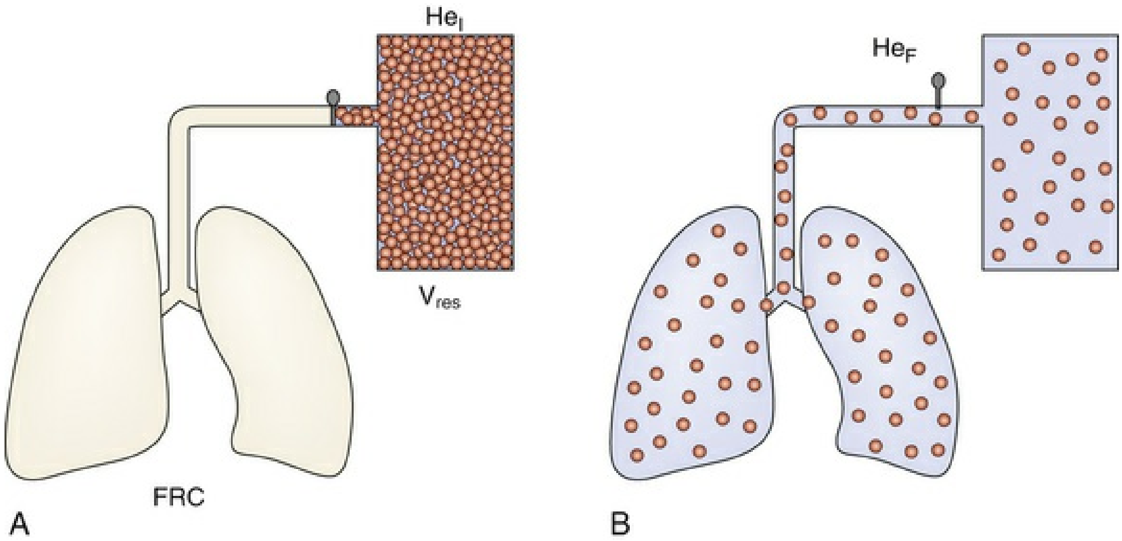

**FIG. 11.5** Schematics of the helium dilution technique. (A) Lung and reservoir filled with air and a mixture of helium (He), respectively. (B) Equilibration of He in the respiratory system and the reservoir. *FRC,* Functional residual capacity; *He$_F$,* final He concentration; *He$_I$,* initial He concentration; *V$_{res}$,* volume of the reservoir $He_F = He_I \times V_{res}/(V_{res} + FRC)$. See text for details.

$$He_I \times V_{reservoir} = He_F \times (V_{reservoir} + FRC_g)$$

where $He_I$ is the initial and $He_F$ is the final concentration of He that is measured with a gas analyzer. The correction for the deadspace volume (facemask or mouthpiece and the switching valve) and the BTPS (body temperature, pressure, saturated) adjustment of the results are crucial for the calculation of $FRC_g$. The circuit has to be leak free; therefore $O_2$ has to be continuously added to the system while $CO_2$ is being absorbed throughout the test.

With the commercialization of MBW, the parallel measurements of $FRC_g$ and ventilation inhomogeneity have become more popular in both preschool-age children and infants. The details of the MBW technique are discussed in the *Measurements of Gas Mixing* part of this chapter. Briefly, $N_2$ washout with pure $O_2$ is the most common MBW test in preschool-age children. $N_2$ is already present in the lungs in a concentration of about 80%, which is decreasing with every breath that the child takes of pure $O_2$. The concentration of $N_2$

as well as the tidal flow is recorded throughout the test. (In the commercial devices, the concentration of $N_2$ is measured indirectly: the level of $CO_2$ and $O_2$ are detected in the exhaled air and the quantity of $N_2$ is calculated secondarily.) $FRC_g$ is calculated as the product of the net volume of the inert gas exhaled during the test and the difference between the end tidal $N_2$ concentration at the beginning and at the end of the test, assuming that FRC was stable throughout the test. FRC can also be calculated for each breath separately. $SF_6$ is frequently used as a tracer gas in infants to avoid the effect of pure oxygen on the breathing pattern and respiratory mechanics. The value of $FRC_g$ is usually lower when extrinsic tracer gases are used (such as He, $SF_6$), since $N_2$ is also excreted from the tissues, which affects the concentration of $N_2$ within the lungs.[16]

## Quality Control, Acceptability Criteria, and Limitations

The quality control, the acceptability, and the limitations of the MBW test are discussed in the *Measurement of Gas Mixing* part later in this chapter.

Generally, the main acceptability criteria of the different gas dilution tests are independent of the test gas, and it is always desirable to have at least three recordings with $FRC_g$ within 25% from each other; however, two tests within 10% may also be acceptable.

Similarly to plethysmography, the test requires a stable breathing pattern, which is difficult to achieve in unsedated infants and young children. Further complications are caused by the use of the facemask because of the difficulty in controlling leaks around the mask. While bigger leaks are usually identifiable by a quick drop in the concentration of the tracer gas during the washout phase of MBW or throughout the He dilution test, small leaks are difficult to recognize, and the risk of reporting false data increases. If the differences in $FRC_g$ between successive tests are bigger than 25%, the examiner should always check the system for leak, which is usually resolvable with the replacement of the facemask. Real-time quality control is therefore of utmost importance during the gas dilution test.

Although the gas dilution tests are relatively easy to perform, $FRC_g$ only reflects the parts of the lungs that are ventilated and communicating directly with the airway opening. Therefore true FRC can be underestimated with lung disease; this remains one of the main limitations of the technique.

## Interpretation of Lung Volumes in Infants and Young Children

Longitudinal measurement of lung volumes in healthy subjects provides information on lung development and growth; however, this is not necessarily true in children with lung disease. In healthy children, FRC correlates with height (Fig. 11.6)[17] and weight, and it is frequently reported as a normalized value for body weight (mL/kg), especially during infancy. Despite the unstable end-expiratory lung volume (EELV) in neonates and infants, the relationship between body weight and FRC is relatively strong in early life. It is a common observation that there is a difference between plethysmographic and gas dilution estimates of FRC, although this difference becomes relatively smaller with growth in healthy children.[18] Since the normative values reported in older infants and young children are highly influenced by the device and the methodology used for the measurement of FRC, it is recommended to measure FRC in *healthy* subjects in each laboratory to aid the interpretation of the FRC data in children with lung disease. If reference values are available, the relevance of that given dataset (i.e., same device, similar population characteristics, similar data analysis, etc.) has to be investigated carefully.

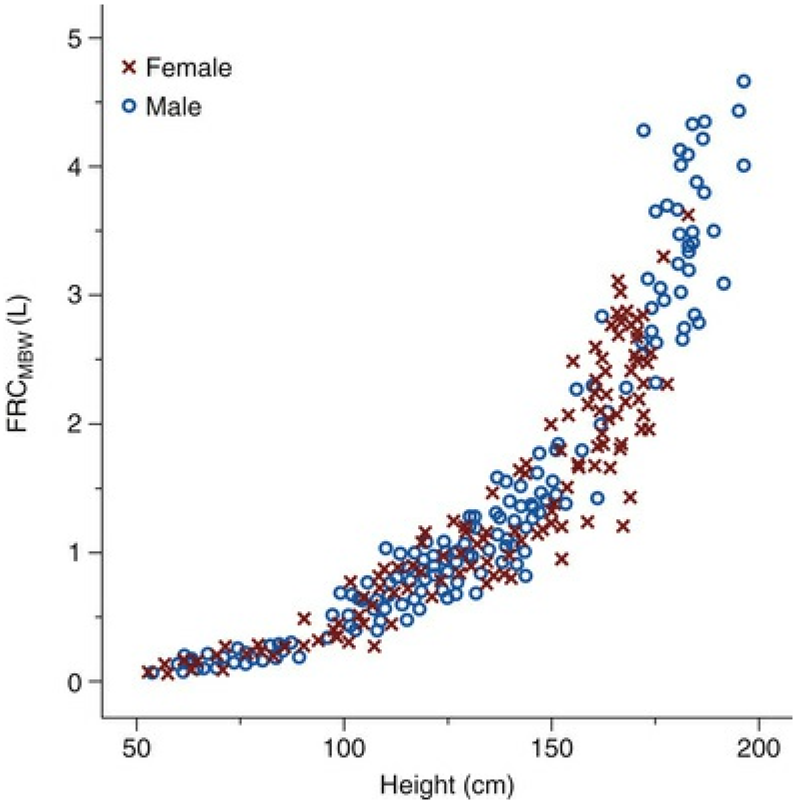

**FIG. 11.6** Relationship between functional residual capacity (FRC) measured by multiple-breath washout (MBW) and body size. (Lum S, Stocks J, Stanojevic S, et al. Age and height dependence of lung clearance index and functional residual capacity. *Eur Respir J*. 2013;41(6):1371-1377.)

Both restrictive and obstructive lung diseases affect the value of FRC directly; however, this effect can be distorted because of the different limitations of the measurement technique.[6] FRC can be underestimated with the gas dilution technique in the presence of air trapping[18,19]—or overestimated if FRC is measured with the plethysmographic method in severe airway obstruction.[12]

One of the most common reasons for low FRC during infancy is surfactant deficiency in preterm babies (respiratory distress syndrome), which results in atelectasis with low lung volumes and low respiratory compliance.[20] In studies on bronchopulmonary dysplasia (BPD) low FRC has been reported during infancy[19–21] (in most of the studies FRC has normalized later in life). Lung volumes can also be diminished in conditions that affect the chest wall such as muscular disease or chest wall deformations and in congenital diaphragmatic hernia.[22] Some of the autoimmune diseases cause restrictive pattern in the lungs resulting in lower FRC, RV, and TLC with a marked decrease in diffusion capacity of carbon monoxide (DLCO, see also in the DLCO part of this chapter).[22a–22d]

Airway obstruction is the most common mechanism underlying the changes in FRC in both infants and young children.[19,21,23] Depending on the severity of the obstruction, dynamic hyperinflation may result in increased FRC and can be detected with both the plethysmography and the gas dilution technique. In contrast, closure of the peripheral airways and the consequent air trapping during expiration does not modify the $FRC_p$, whereas trapped air is not included in the value of $FRC_g$ (see explanation above). Bronchiectasis-related increase in FRC, RV, and TLC are often present in older children with CF or primary ciliary dyskinesia (PCD), and the increase correlates with the extent of the bronchiectasis and air trapping on the chest CT.

The measurement of FRC is fundamental for the understanding and interpretation of respiratory mechanics; however, it is important to note that FRC is unstable in infants and also highly variable in preschool-age children; therefore the interpretation of a low or high FRC without other measures of lung function has limited clinical value.

The knowledge of FRC is particularly important in the plethysmographic measurement of airway resistance, which is commonly reported as $sR_{aw}$ ($R_{aw}$ normalized for the FRC); this will be discussed in the *Measurement of Respiratory Resistance and Compliance* part later in this chapter.

## Measurement of Diffusing Capacity of Carbon Monoxide

### Summary

- It is called transfer factor of carbon monoxide ($T_{LCO}$) in Europe and diffusing capacity (DLCO) in the United States
- It provides information on the rate at which the

oxygen is transferred via passive diffusion from the lungs to the circulation

- The diffusion across the alveolar-capillary interface can be impaired by both structural and functional changes of the alveoli or the capillaries
- Except for a few research studies in infants, the measurement of diffusion is only performed in cooperative, older children
- New measurement guidelines using rapidly responding gas analyzers (RGA) and robust reference values for the Caucasian population (over 5 years of age) have recently been published. Commercial devices are available

As a very important part of gas exchange, oxygen has to transfer from the alveoli to the capillaries. Oxygen travels through the alveolar-capillary barrier via passive diffusion and the rate is highly determined by structural and functional properties of this system. However, oxygen transfer through the lungs cannot be determined directly.

## Physiological Principles and Assumptions

Carbon monoxide (CO) is a gas perfectly designed to measure diffusion from the lungs to the circulation. As there is no CO in the blood (except in heavy smokers), even at low concentrations, CO transfers from the alveoli to the capillaries driven by the pressure difference between the partial pressure of CO in the alveoli ($P_{ACO}$) and the capillaries ($P_{aCO}$). CO has an enormous ability to bind with hemoglobin (hb) in the vessels, and hb becomes fully saturated even at very low partial pressures. During this transport, the partial pressure of CO changes in the blood to only a minimal degree. Therefore diffusion is the only limiting factor for CO uptake into the blood and CO has been used to assess diffusion for many decades.

The rate of transfer of carbon monoxide from the alveoli to the pulmonary capillaries is a strong indicator of the efficiency of gas exchange in the lung. This recognition resulted in the development of a new lung function method. Although the measurement of diffusion via CO intake was introduced over 100 years ago,[23a] it was first standardized for clinical testing in the late 1950s.[23b] DLCO is an indicator of all the main determinants of diffusion such as the area and thickness of the alveolar-capillary barrier and the diffusion constant of the measured gas. It can be defined as the conductance of CO from the inspired gas from the alveolar space to the hb-binding sites within the capillaries. Since all the technical details of the measurement method have been published in-depth recently (see *Suggested Reading*),[23c] only the main principles and interpretation of the test are summarized in this chapter.

During the test, after a few tidal breaths, the child is asked to exhale to RV. According to the recently published recommendations, the expiration time can be as long as 12 s. Because of their smaller lung volumes it is easy for children to empty the lungs over 12 s, even in the presence of severe obstruction. Then, the child is instructed to take a deep, quick breath of a gas mixture containing 0.3% CO, a tracer gas (usually 10% He or 0.3% neon), 21% oxygen and the balance as nitrogen. It is assumed that CO reaches the alveolar space instantly and the alveolar concentration of CO changes rapidly by mixing with the gas volume in the lungs (i.e., RV). The volume of CO in the lungs will be a product of the alveolar volume ($V_A$) and the fractional concentration of the CO in the alveolar space ($F_{ACO}$). The volume of the inspired gas should be close to VC (between 90% and 95%). A suboptimal inspiration (i.e., less than 85% of VC) affects the alveolar volume significantly and hence the DLCO values (see below). Since the assumption of the test is that CO reaches the lungs instantaneously, rapid inspiration is an important acceptability criterion in the measurements of DLCO. Once the child reaches full inspiration, the breath should be held for about 10 s. The proper breath-hold is one of the most difficult parts of the measurement of DLCO. Since both increased and decreased blood flow and alveolar surface area affect diffusion, the breath-hold needs to be voluntary and without effort. Müeller and Valsalva maneuvers should therefore be avoided (see below).[23d] Following the breath-hold, the child should exhale immediately with a smooth, relaxed expiration. During the maneuver, modern RGA systems can provide continuous monitoring of the concentrations of CO and the tracer gas as well as the volume over time. However, the analysis of the gas is often performed the same "classical" way as in the older systems. The unit of DLCO is traditionally $ml.min^{-1}.mmHg^{-1}$ in the United States, while in Europe the SI unit is preferable ($mmol.min^{-1}.kPa^{-1}$). Changes in both the structure and function of the alveolar-capillary interface can alter the diffusion of CO, making the interpretation of the results less straightforward.

## Quality Control, Acceptability Criteria, and Limitations

The technical details of the measurement setting, gas analyzers and quality control criteria are discussed in detail in the newest guideline and they are outside of the scope of this chapter. Once children can cooperate with the respiratory maneuver necessary for the test, the measurement is quick and easy to perform. In small children, when the VC is less than 1.5–2.l, cooperation is not the only limitation; the measurement can be invalid because of the small volumes and technical modifications should be considered.

Physiological increases or decreases in DLCO and conditions that influence the diffusing capacity that are unrelated to the respiratory system make the interpretation of the results difficult. This remains the main limitation of the test and is discussed in detail below.

## Interpretation of DLCO

The largest set of reference values for DLCO has been established for the Caucasian population from 4 to 91 years of age.[23e] This dataset includes the recently published children-specific reference values (ref Kopman 2011, Kim 2012).[23f,23g] When body weight-adjusted dead space correction was applied to the data, the between site differences in the pediatric values were minimized. The main predictors of DLCO were age, height, and sex and z-scores were created for both males and females. Between 4 and 18 years of age, the absolute value of DLCO increases steeply, while DLCO decreases after 30 years of age. Therefore, DLCO should always be reported as z-scores, using the new Global Lung Function Initiative (GLI) equations in Caucasian children. A physiologically relevant change in DLCO was defined as 0.5 z-score or 10% relative change (around 0.3–0.8 $\text{mmol.ml}^{-1}.\text{kPa}^{-1}$, which is equal to 0.9–2.4 $\text{ml.min}^{-1}.\text{mmHg}^{-1}$). Lower limit of normal (LLN) is frequently used to define abnormal lung function and has been defined as below the 5th percentile of the dataset. Since increased DLCO values usually have limited clinically relevance, and the increase is often physiological, an upper limit of normal (ULN) was not established. Adjusting for hb levels had no significant effect on the z-scores, but hb concentration should be considered, especially in patients with anemia. Recommendations for altitude-correction have also been established.[23c,23e]

Physiologically, there are factors that affect the value of DLCO and they can complicate interpretation of the test. One of these factors is increased pulmonary blood flow, which can increase the value of DLCO. This occurs in exercise, via the recruitment of new pulmonary capillaries. In patients with lung fibrosis, the exercise-dependent increase in DLCO is usually missing and this characteristic feature of lung fibrosis can aid the diagnosis. Increased intrathoracic pressure, such as the Müeller maneuver, increases the alveolar surface and hence DLCO; therefore it is important that the child should hold their breath with minimal effort during the test. Hormonal changes in women can also affect the measurement; DLCO is greatest just before menses with high intrasubject variability, while girls in their prepuberty are able to produce a more stable DLCO with minimal variation. The lowest value of DLCO is measured on the third day of menses.[23h]

Cigarette smoke can decrease DLCO due to the increase in the COhb in the blood, which increases the back pressure of CO.[23i] Therefore a smoking history should always be collected from older children and, in the case of regular smoking, they should be asked to refrain prior to the test. Other nonpulmonary diseases can also influence the diffusing capacity. Increased (e.g., polycythemia) or decreased (e.g., anemia) hb levels can either increase or decrease DLCO, respectively. Left-to right cardiac shunts also increase the blood flow and hence DLCO.

Uneven distribution of ventilation-perfusion in the lungs can reduce DLCO. Since CO only reaches the areas of the lungs where there is ventilation, alveolar volume and hence DLCO can be underestimated in severe airway obstruction. When lung emptying becomes nonhomogeneous, the discrimination between the conductive and alveolar gas can be altered and the sample one takes might not be reflective of the alveolar gas compartment. Since diffusion of CO only happens in areas of the lungs where there are both ventilation and perfusion, if perfusion is diminished in an area it can decrease the global value of DLCO. This can be the case with pulmonary emboli or pulmonary hypertension. However, it is well established that when perfusion is limited in a part of the lungs, perfusion can increase in other parts to maintain normal gas exchange. This is why in pneumonectomy (when the cardiac output flows through a single lung and new capillaries are recruited) DLCO does not decrease to 50% of the original value.

DLCO is most informative in interstitial lung disease (independently of the mechanism of fibrosis) and measurement of CO diffusion is one of the most common tests in this patient group. DLCO has also been shown to be useful in lupus erythematosus, scleroderma, sarcoidosis, and other lung disease that affect the alveoli such as alveolar proteinosis. DLCO can be elevated in obstructive lung disease, keeping in mind the limitations regarding severe obstruction as discussed above.

## Measurement of Forced Expiration

Measurement of flow and volume during forced expiration from total lung capacity (TLC) is the most frequently used lung function test in clinical practice in both children and adults. After proper training, 50%–80% of preschool-aged children are able to perform acceptable spirometry, but interpretation of the forced expiratory measures is less straightforward than in adults. To further extend the measurement of forced expiration, two techniques have been developed specifically for the use in infants. Since infants are not able to perform a forced expiratory maneuver, flow-volume curve can only be obtained by rapidly applying pressure around the infant's chest and abdomen with an inflatable jacket during tidal breathing (rapid thoracoabdominal compression [RTC]) or after inflation of the lungs to TLC (raised volume RTC: RV-RTC). These tests still remain the most commonly performed lung function techniques in infants in a clinical setting.

The underlying physiological principles apply for both the infant techniques and the conventional spirometry; therefore they will be discussed together.

## Physiological Principles and Assumptions

The basic finding underlying clinical use of the forced expiratory flow volume curve was established in the 1950s when transpulmonary pressure and flow were measured in parallel at isovolumic conditions in adults.[24] Subjects were sitting in a plethysmograph while an esophageal balloon was employed to detect the transpulmonary pressure continuously, and they were asked to breathe at a given lung volume with increasing effort. While at high lung volume the flow increased easily with the driving pressure, at low lung volumes flow could not increase any further even if the transpulmonary pressure increased (Fig. 11.7). This phenomenon is called flow limitation. Following this observation it did not take long to realize that forced flow-volume curves and hence flow limitation can be achieved during forced expiration across a wide range of lung volume (from TLC to RV) without the need to measure transpulmonary pressure.[25] The maintenance of flow limitation is fundamental to the interpretation of forced expiration and this can be difficult at very high and at low lung volumes. Most adults and older children can achieve and maintain flow limitation in the mid-range of lung volumes and this determines the clinical application of spirometry.

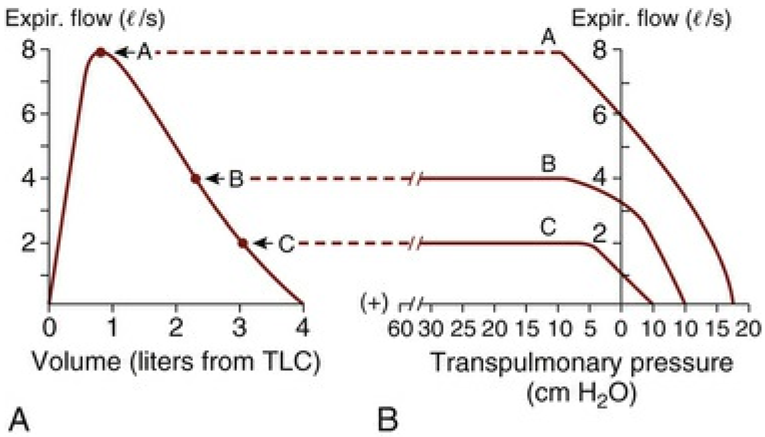

**FIG. 11.7** Three isovolume pressure-flow curves from normal subject are shown in panel B. Curves A–C were measured at volumes of 0.8, 2.3, and 3.0 L, respectively, from total lung capacity (TLC). Transpulmonary pressure is the difference between pleural (estimated by esophageal balloon) and mouth pressures. Panel A is flow-volume plot for same subject. Maximal expiratory flows are plotted vs. their corresponding volumes as points (0) A–C and define maximal expiratory flow-volume curve *(solid line).* See text for details. (Hyatt R. Expiratory flow limitation. *J Appl Physiol Respir Environ Exerc Physiol*. 1983;55:1-8.)

When the expiratory muscles are maximally activated at a high lung volume, the pleural pressure is suddenly raised and this rise is transmitted to the alveoli. However, this pressure rise also changes the transmural pressure of the bronchi and tries to decrease their lumen (Fig. 11.8). Thus, both emptying the lung and obstructing the pathway to the airway opening are driven by the same (maximum) expiratory effort. The two opposing processes determine a dynamic equilibrium resulting in flow limitation. If the airways were rigid, the decrease of expiratory flow would occur gradually because of the loss of force that can be generated by the muscles at decreasing lung volumes. The additional drop in flow is the result of the collapsibility of the airways (or certain segments). Flow limitation occurs when, at a given lung volume, the increase in transpulmonary pressure cannot increase the flow any further. Expiratory flow becomes highly turbulent and passes the narrowed airway segment at a very high velocity. The relationship between the flow and volume during a forced expiratory maneuver shows a characteristic shape in healthy subjects (Fig. 11.9A). At the very beginning of the maximum expiration the airflow fast reaches its maximum value (called peak expiratory flow) and then turns into a gradual decrease. The progress of lung emptying (the increase in expired volume) is associated with the fall in expiratory flow until the latter stops on reaching the RV. This *association between flow and volume* during the forced expiratory maneuver is very strong and can be highly reproducible within a subject, provided the starting lung volume and the maximum expiratory effort are consistently maintained in the successive maneuvers. Intuitively, the key issues are (1) how collapsible are the bronchial segments, (2) where is the most collapsible segment (the “choke point”) in the airway tree, and (3) how different are the mechanical properties of the lung regions in the emptying process. Indeed, the diverse patterns of emptying observed in the different lung pathologies (see Fig. 11.9A) are associated with these structural-functional aspects. Since the lung emptying happens much faster in young children, the measurement of forced expiration does not always provide meaningful clinical information even if the maneuver was performed correctly.[26] Narrowing of airways due to inflammation, mucus production, bronchoconstriction, and airway wall remodeling potentiate the bronchi for the flow limitation to occur at relatively high lung volumes, and loss of the tethering forces in an emphysematous lung facilitates airway collapse. This means that the expiratory flow drops faster with expiratory volume, the flow-volume diagram becomes concave, and the lung emptying is delayed (Figs. 11.9A and 11.10). Several indices derived from the maximum expiratory flow-volume curve have been suggested for characterization of the types and degrees of flow limitation (Fig. 11.9B), among which the volume expired in the first time segment ($FEV_t$), for example, in the 1st second ($FEV_1$), is the most commonly measured index (see also in the *Interpretation and Clinical Application* below).

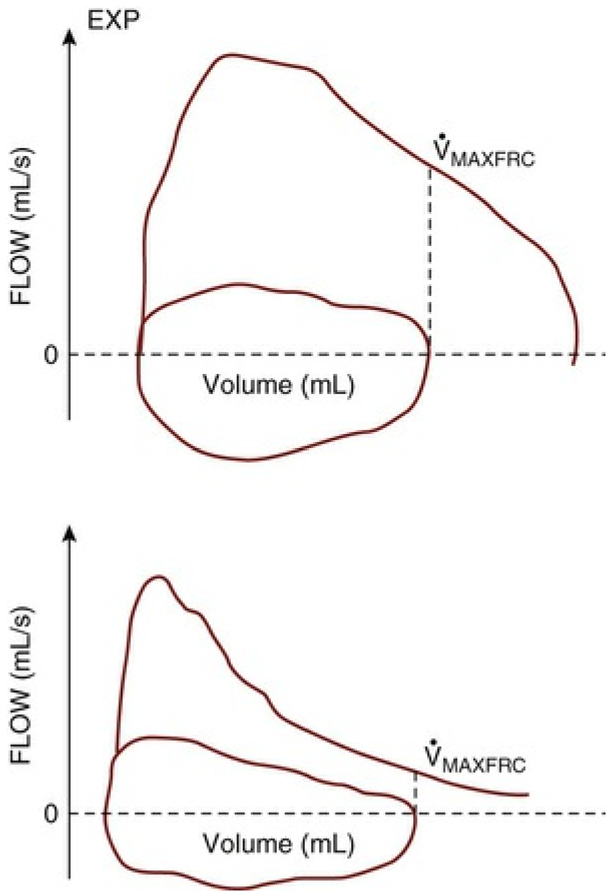

**FIG. 11.10** Partial expiratory flow volume curves measured with the Rapid Thoracoabdominal Compression technique. Smaller inner curve represents tidal breathing, and larger curve represents maximal expiratory flow generated by rapid compression technique. Maximal expiratory flow at functional residual capacity ($V'_{max,FRC}$) is indicated by dashed line. Difference between tidal breathing and maximal expiratory flow represents expiratory flow reserve. (A) Normal control infant has convex to linear maximal expiratory flow volume curve, with large expiratory flow reserve. (B) Infant with bronchopulmonary dysplasia has concave flow volume curve, with decreased expiratory flow reserve and $V'_{maxFRC}$, compared with A. (Tepper RS, Morgan WJ, Cota K, et al. Expiratory flow limitation in infants with bronchopulmonary dysplasia. *J Pediatr*. 1986;109(6):1040-1046.)

## Measurement of Forced Expiratory Flow and Volume in Cooperative Subjects

## Summary

- Spirometry remains the most common lung function test both in children and adults
- Flow is measured during forced expiration from TLC to RV and a flow-volume curve is constructed
- Success rate is above 85% in children older than 6 years of age
- The main outcome measures reported in older children are: forced vital capacity (FVC), $FEV_1$, $FEV_1$/FVC, forced expired flow between 25% and 75% of expired FVC ($FEF_{25-75}$).
- In young children, acceptability criteria differ from those in older children or adults
- With appropriate training 50%–80% of preschool-aged children are able to perform spirometry although $FEV_1$ is not the best outcome variable
- If expiration is long enough, $FEV_t$ can be acceptable while forced vital capacity (FVC) and consequently $FEF_{25–75}$ and flows at fixed lung volumes may not be valid in preschool-age children
- Clinical usefulness of the forced expiratory flow and volume variables remains controversial in young individuals with lung disease

Spirometry is the most commonly used lung function method in cooperative children (usually above 6 years of age) and it remains very popular amongst clinicians. The interpretation of the forced expiratory flow-volume curve in children during the teenage years is very similar to that in adults. In the last two decades it has also become evident that children below 6 years of age are able to perform acceptable spirometry after appropriate training.[26–34] Although forced expiratory maneuvers are feasible, the acceptability criteria and the interpretation of the flow and volume measures are different from those in older children and adults. Later in this chapter, the age-specific limitations, quality criteria, and interpretation of the measures derived from the flow-volume curve will be discussed.

## Quality Control, Acceptability Criteria, and Limitations

The criteria for acceptable spirometry are less strict than those in adults; therefore the subjective impression of the technician becomes exceptionally important. The success of the test depends on the effort of the child who has to be continuously instructed and encouraged throughout the maneuvers. If the effort was insufficient, the test is invalid. The "emptying of the lungs" happens much faster in young children than in adults, and the termination of the test differs between individuals. For a valid test, older children and adults are required to exhale at least for 6 s, to accurately determine FVC. This is called the plateau phase of the flow-volume curve, during which the volume is not changing anymore with time. In preschool-aged children a 3-s-long plateau can be accepted; however, young children can usually empty their lungs quicker than 3 s. The technician should be able to recognize whether the child reached RV or finished the expiration too early (so-called premature termination). Premature termination occurs if the expiration is stopped at a flow greater than 10% of the peak flow. Premature termination is the most common reason of unsuccessful test in children, which can be improved with training. In young children FEVt can still be acceptable if they reached RV earlier than 3 s, while FVC should be reported with caution. Artefacts (e.g., cough) are usually recognizable by observation of the flow-volume curve.

The exclusion criteria and the data reporting are fairly consistent in older children, they vary between centers in preschoolers. Three acceptable measurements are desirable; however, the recommendations are flexible on this question.[27] In special cases it should be considered that clinically meaningful information can sometimes be gained from a single successful maneuver. Highest values for FVC and $FEV_t$ should be reported, even if they do not belong to the same maneuver. The reproducibility of spirometry in preschool-age children has not been assessed systematically, and this fact contributes to the limited clinical value of spirometry in young individuals (see also the *Assessment of Bronchodilator Response* below).

Prediction equations for spirometry measures have recently been published in the framework of collaboration between 33 countries (Global Lung Function Initiative),[35] which was established to standardize spirometry worldwide. Age-appropriate lower limits of normal are also available.

## Measurement of Forced Expiratory Flow and Volume in Infants

### Summary

- The most common clinical lung function tests during infancy
- Flow-volume curve can be measured at both FRC (RTC) and in an extended range of lung volumes (RV-RTC)
- Commercial devices and reference values are available
- Maximum flow at FRC (RTC) and FVC, $FEV_{0.4/0.5}$, and $FEV_{0.5}$/FVC (RV-RTC) can be reported
- Flow limitation in the intrathoracic airways can be detected with minimal influence of the nasal pathway
- Main drawbacks are the sedation and the controversies in the interpretation of the results

Both RTC and RT-RVC were developed for infant use to extend the knowledge of normal lung growth and development, to aid the diagnosis of acute and chronic pulmonary lung disease, and to allow the longitudinal follow-up of lung function from infancy through adulthood. Recommendations and guidelines are available for both techniques (see *Suggested Reading*).

## Rapid Thoracoabdominal Compression and Raised Volume-Rapid Thoracoabdominal Compression

With RTC, a partial flow-volume curve can be recorded, and the main outcome variable reported is the maximum flow at FRC ($V'_{max,FRC}$, see Fig. 11.10). Although this technique had great clinical promise when first introduced, it has been increasingly criticized, especially after the introduction of the RV-RTC.[36–38] The advantage of the partial flow-volume curve analysis during tidal breathing over RV-RTC is the lack of the unpredictable and variable effects of the lung inflation on the airways.

Infants are usually sedated for the test. They breathe through a pneumotachograph or ultrasonic flow meter that is attached to a facemask. Flow is continuously monitored during the test and volume is calculated by integration of the flow signal. Following the placement of the jacket around the chest and upper abdomen, tidal breathing is recorded for ~30 seconds. Signals of airway-opening pressure, jacket pressure, volume, and flow are displayed real time. A stable EELV is required for at least three consecutive breaths prior to the maneuver; a criterion that is difficult to meet in infants because of their highly variable FRC. Once a stable EELV has been recorded, the jacket is inflated at the end of inspiration with a nonstandardized pressure (30–40 cm $H_2O$, different for each device and center) and the flow at the airway opening is recorded during the maneuver. The test is repeated with increasing the inflation pressure stepwise (5 or 10 cm $H_2O$) until flow limitation can be demonstrated. The pressure required for the development of flow limitation varies between subjects and it is expected to be significantly lower in children with lung disease (flow limitation develops easier), while in some healthy children pressures as high as 120 cm $H_2O$ can be insufficient to evoke flow limitation. It also varies between individuals how much pressure is transmitted to the pleural space from the jacket via the chest wall[39]; therefore comparing the jacket pressure between individuals as the main outcome variable is meaningless. The test finishes when maximum flow has been achieved and no further increase in flow is detected despite the increasing pressure. Similarly to spirometry, the best values of $V'_{max,FRC}$ are reported instead of the average of all the values. Results are sometimes corrected for lung volume ($V'_{max,FRC}$/FRC).

Studies employing an esophageal catheter during RTC have shown that infants can inspire before the end of the maneuver and the chest wall muscle activity can decrease both the intrathoracic pressure and chest wall compliance, resulting in a decreased transpulmonary pressure.[39] It was also shown that if the RTC maneuver was preceded by deep lung inflations, the inspiratory drive of the infant was inhibited.[40] This recognition led to the invention of a new lung function technique: the RV-RTC. This technique is very similar to RTC; however, in RV-RTC the facemask is attached to a T-piece connector (or valves in the modern automatized systems), which contains a valve to separate inspiration and expiration (Fig. 11.11). By occluding the expiratory side of the T-piece, the airway-opening pressure increases until the target pressure (usually 30 cm $H_2O$ but may differ between centers) is achieved, where activation of the stretch receptors in the lungs results in the relaxation of the respiratory muscles; this is called the *Hering-Breuer reflex* (see also in the *Single Occlusion Technique* later in this chapter). At the target pressure the valve opens, which allows the infant to exhale passively. In some centers, cricoid pressure is applied during inflation to prevent the entry of the gas in the stomach. The benefits of this technique, however, have not been addressed systematically and they have been questioned in some studies.[41,42] The inflation/passive expiration is repeated three to five times and then at the next inflation rapid compression is performed (Fig. 11.12). The variables derived from this maneuver are similar to those measured with spirometry in cooperative subjects. In most of the centers where RV-RTC is performed routinely, the measurement of partial flow-volume curve is undertaken first to record $V'_{max,FRC}$ (the measurement of $V'_{max,FRC}$ with RV-RTC is not reliable as the lung inflations can change EELV) and to establish the ideal jacket pressure for the rapid compression in RV-RTC.

## Quality Control, Acceptability Criteria, and Limitations

Once the infant is ready for the lung function test (either RTC or RV-RTC), a jacket matching the infant's size should be selected carefully. The infant is then wrapped in the jacket to cover as much of the chest and the upper abdomen as possible; however, the jacket should not interfere with the breathing of the baby. If the jacket pressure is other than zero, or if it is changing during tidal breathing, then the jacket is too tight.

Following the 30-second tidal breathing recording, a short occlusion should be applied to check the system for leaks. If there is a drop in the airway-opening pressure during the occlusion it indicates an insufficient seal around the facemask, while if flow is detected in the system it suggests a leak through the occlusion valve (or T-piece in RV-RTC). As in other lung function tests, the correct placement of the mask is crucial. Leaks are more frequently present during the inflation phase of RV-RTC when the airway-opening pressure increases. In contrast, pressing the facemask too hard might result in the occlusion of the upper airways (and underestimation of the measured flow).

Artefacts are frequently present during the test. The compression-decompression of the chest might activate muscle and respiratory reflexes, resulting in muscle constriction and sometimes glottic closure during the test. The latter is easily recognizable by the observation of the flow-volume curve. Respiratory reflexes (e.g., early inspiration) can also interfere with the measurements. Negative effort dependence, with decreasing expiratory flows and a concave flow-volume curve, can be seen if the jacket pressure is too high, leading to external compression of the chest wall and large intrathoracic airways.

Normative values are available for both techniques, and device-specific reference values have been published recently for RV-RTC (Fig. 11.13).[43] *Z*-scores have also been calculated for a mainly Caucasian population. If *z*-scores are not relevant for the measured population, absolute values should be reported instead of the percent predicted values. Values of forced expiratory flows and volumes measured with RTC and RV-RTC show a markedly nonlinear relationship with body length and weight and a linear relationship with age during infancy.[44] Interestingly, forced expiratory flows are generally higher in girls than boys.[44]

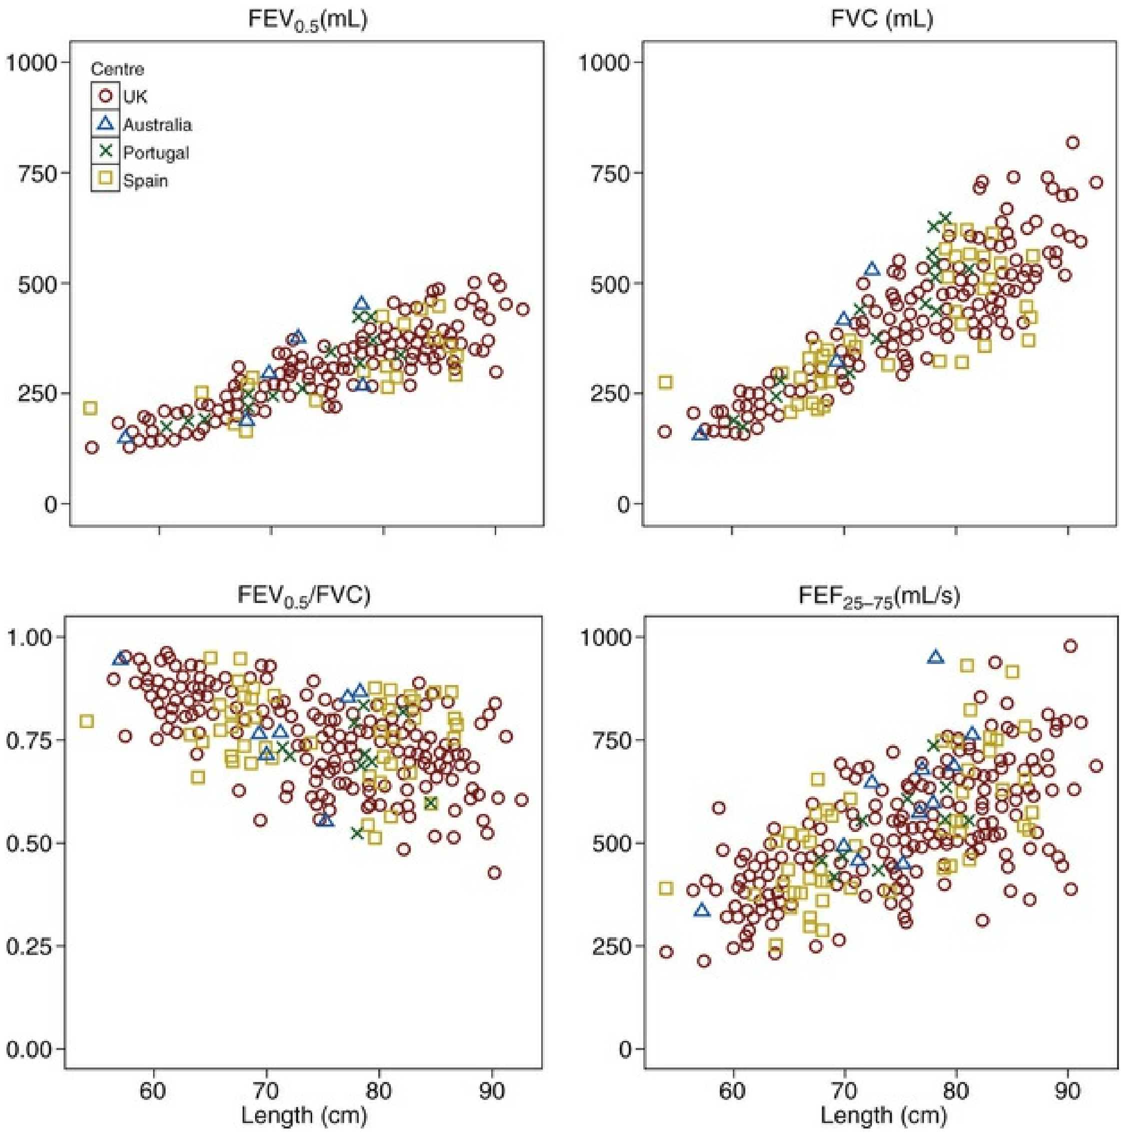

**FIG. 11.13** Forced expiratory flow volume (FEFV) measured with the raised volume rapid thoracoabdominal compression technique using commercial equipment in four different centers (United Kingdom, Spain, Portugal, and Australia). (Lum S, Bountziouka V, Wade A, et al. New reference ranges for interpreting forced expiratory manoeuvres in infants and implications for clinical interpretation: a multicentre collaboration. *Thorax*. 2016;71(3):276-283.)

If multiple lung function tests are performed in the same infant, RTC or RV-RTC should be performed as the last tests, because these radical pressure changes may influence the baseline respiratory mechanics and measurements of ventilation inhomogeneity. It has recently been published that the inflation/compression maneuvers necessary for RV-RTC affect the value of lung clearance index (LCI) measured with MBW (LCI is lower after the maneuver).[45] However, if the most relevant clinical (or research) question is related to the forced expiratory variables, it always has to be considered that the time of the proper sedation (30–45 minutes) might not be sufficient to undertake multiple lung function tests. In this case (RV-) RTC may need to be prioritized.

## Rapid Thoracoabdominal Compression-Specific Considerations

Once acceptable flow-volume curves are detected, the best value for $V'_{max,FRC}$ should be reported and it is desirable if it is within 10% from the second highest value. From the three best measurements the coefficient of variation (COV: 100[SD/mean]) can be calculated. The values of COV are usually higher than 10%, which is likely to be explained by the changes in the absolute lung volume between measurements (even if EELV was reproducible within one test).

## Raised Volume-Rapid Thoracoabdominal Compression-Specific Considerations

The jacket pressure has to be selected carefully, since if the jacket pressure is not high enough, it will decrease the value of $FEV_t$ (while it may not affect FVC); if the jacket pressure is too high, it can cause airway obstruction.

The test is technically acceptable if the relaxation is complete and it lasts until RV is reached. This is easily recognizable by visual observation of the flow-volume curves. A test meets the quality criteria if it is artifact-free (no closure, no inspiratory effort, etc.) and if the peak flow is achieved before 10% of the volume is expired. At least two technically acceptable maneuvers with FVC (and $FEV_t$) within 10% are required for a meaningful interpretation. Forced expiratory volumes and flows are reported from the best maneuver.

## Interpretation and Clinical Application of the Flow-Volume Curve

Independently of the patient's age and the technique used to assess forced expiratory flows or volumes, the flow-volume and the volume-time curves should always be observed carefully. This is crucial for the correct interpretation of the test. The interpreter should be able to recognize if the maneuver was not performed correctly, be aware of the presence of artefacts, and—if the examiner is experienced enough—the shape of the curve can provide unique clinical information (Fig. 11.9A).

While $V'_{max,FRC}$ is the most commonly reported measure of the RTC, various outcome variables have been obtained from RV-RTC. The relevance of $FEV_1$ in infants and preschool-aged children has been questioned because of the anatomical and physiological differences in the respiratory system between infants and preschool-aged children and adults. In infants, the airways are relatively big compared to the lung volumes; therefore the emptying during a forced expiration happens much faster (the lungs are basically "empty" after the first second). Therefore the most commonly reported variable is the $FEV_{0.5}$,[43,44] which reflects the expired volume over the first 0.5 seconds of a forced expiration. In preterm infants and neonates, $FEV_{0.4}$ has also been introduced.[46,47] In preschool-age children it is still undecided which variable should be reported from the flow-volume curve. Although $FEV_1$ has been commonly used in both clinical practice and research studies,[26,30–32,34] $FEV_1$ has proven insensitive for airway obstruction in children below 6 years of age.[26,48] As a consequence, reporting the FEV values either for 0.5 or 0.75 seconds has become more popular over the last years.[28,29,33,48,49] In older children, $FEV_1$ is the most commonly reported measure of lung function and has been used worldwide to aid the diagnosis or to track the progress of lung disease. Healthy subjects are able to empty about 80%–90% of their FVC in the 1st second of a forced expiration. In the presence of airway obstruction, flow limitation appears at higher lung volume delaying expiration. A normal or increased FVC with a decreased $FEV_1$ and hence an $FEV_1/FVC$ ratio below 80% (or −1.64 z-score) suggests airway obstruction. In contrast, diminished FVC and $FEV_1$ with a normal (i.e., >80%) $FEV_1/FVC$ ratio usually reflect restrictive lung disease (if the forced expiratory maneuver was performed correctly). $FEV_1/FVC$ has been reported as a more sensitive indicator of early lung disease than $FEV_1$ alone.[49a] The ratio of $FEV_t$

to FVC as a measure of airway obstruction offers very limited clinical potential in children below 6 years of age. As discussed above, this is most probably due to the anatomical and physiological differences in the respiratory system between children and adults and hence an invalid FVC. It is important to note that the $FEV_t$ values, whichever t is selected for the analysis, cannot be directly compared between infants and older children. Additionally, when longitudinal measurements of forced expiratory flow are interpreted, it has to be considered that infants were measured during sedation in the supine position and the measurements were obtained through a facemask.

From the measures of the forced expiry flow, $FEF_{25-75}$ was suggested as a measure of small airway function and a sensitive marker of early disease.[49b] This value is read as the slope of the line connecting the points between 25% and 75% of the expired FVC and it represents the mid-portion of forced expiratory maneuver. This site of the flow limitation is assumed to reflect small airway obstruction; however, the usefulness of $FEF_{25-75}$ is still under debate especially in children. It is highly variable in children, and a recent study reported that $FEV_1$/FVC was more sensitive to detect early disease in both CF and asthma in children above 6 years of age.[49a] The other popular measure of flow during forced expiration is the maximum or peak expiratory flow (PEF). This can even be measured with a peak flow meter where the child is instructed to take the biggest possible inspiration and blow out as quick and hard as they can. Variabilty in PEF was suggested as an indicator of poor asthma control[49c] and hence this test is still frequently included in the clinical management of children. However, it is still not well-established how much this information adds into the clinical management of an individual. The device is cheap and once the child learns the technique it is easy and quick to perform daily even at home. The best of 3 or 5 attempts should be recorded.

In children with cystic fibrosis (CF) the clinical application of spirometry is controversial.[28,29,30,50] It has been shown that structural lung disease begins in early life and can be seen on a chest computed tomography (CT) scan in preschool- and school-aged children with CF while their spirometry results are still normal.[50] Despite this fact, spirometry is used in most studies of CF, and forced expiratory flow and volume measures are still the main outcome measures in clinical trials. It has been recognized in recent years that other lung function tests (e.g., MBW) might be more useful in detecting abnormalities of the respiratory system in early CF.[51–53] Despite these controversies, spirometry is considered the standard test for monitoring lung disease in CF to detect changes in lung function or response to treatment. $FEV_1$ is traditionally included in the evaluation protocols for lung transplantations in CF-related terminal lung disease: an $FEV_1$ value below 30% predicted is one of the indications to be placed on a lung transplant waiting list.[53a,53b] Following lung transplantation, repeated spirometry is the only lung function test that is routinely performed to diagnose chronic allograft dysfunction, even if it does not seem to be the most sensitive test to detect bronchiolitis obliterans.[53c] In contrast, the RV-RTC method has provided meaningful clinical information on flow limitation in infants with CF.[36,54–57] Since newborn screening of CF is routinely performed in many countries worldwide, the need for a sensitive lung function test that detects early lung disease, does not require sedation, and can be undertaken easily and safely in young children is high.

In young wheezy and asthmatic children, significantly lower values of $FEV_{0.5}$ and $FEV_{0.75}$ have been reported compared to those in healthy children; however, it is unclear how informative the spirometry is in the clinical management of an individual. It is likely that the test is more useful in “older” preschoolers (i.e., 5 and 6 years of age) and school-age children, and their longitudinal follow-up with spirometry provides important information on the progression of their lung disease. The correct interpretation of abnormal lung function in older children can confirm the diagnosis of asthma. These indices include (1) a low $FEV_1$ (below −1.64 z-score), (2) a low $FEV_1/FVC$ (below −1.64 z-score), and (3) an exaggerated variability in PEF (morning-to-evening more than 20%). Children do not always have airflow limitation on the day of the test and their lung function is often normal when measured with the spirometry between two exacerbations. Therefore it is worthwhile to perform BDR or bronchoprovocation test: a positive BDR (see below) or a confirmed bronchial hyperresponsiveness (see

Chapter 12) can support the diagnosis of asthma. It has recently been suggested that different obstruction phenotypes defined with spirometry are related to different risk of poor asthma outcomes such as exacerbation or medication use in children.[57a] In poorly controlled or severe asthma, deep inspiration and forced expiration per se can induce bronchospasm and worsen lung function. This is rarely seen in children and when it is present it is difficult to produce reproducible flow-volume curves. Decreasing $FEV_1$ with each maneuver can be a sign of severe asthma and should be interpreted accordingly. It is important to note here that spirometry can be very difficult and tiring to perform for children with severe lung disease and alternative tests should be considered. Interestingly, it has been suggested that variables derived from the forced expiratory flow-volume curve during infancy (both during tidal breathing and following lung inflation) not only discriminate between health and disease, but also that the early presence of flow limitation predicts lung disease later in life[47,58,59] Attempts have also been made to assess bronchial hyperresponsiveness in wheezy infants[60–63]; however, it remains unclear whether it adds any value to the clinical management of individuals.

In research studies, variables derived from the spirometry are the most commonly used outcome measures in clinical trials, studies on lung growth and development, and classification of wheezy and asthmatic children.

## The Assessment of Bronchodilator Response

The assessment of the response to albuterol is one of the most frequently performed tests in both clinical practice and research studies. The main limitation of the measurement of bronchodilator response (BDR) in infants and preschool-age children is the high intrasubject variability of the forced expiratory flow-volume curves, which makes the characterization of the bronchodilator-related changes in lung function difficult. Since the forced flow-volume curve is highly reproducible in older children, this problem is far less significant.

In infants, the therapeutic use of albuterol was questioned for a long time because of the lack of objective and sensitive lung function techniques in early life. Since RTC is able to detect flow limitation, it had great promise in the assessment of diagnostic or therapeutic drug interventions. Unfortunately, these tests have revealed the most important clinical limitation of the test: the uncontrollable changes in the absolute lung volume following an intervention. A stable EELV is required for the proper interpretation of the results; however, this is difficult to achieve in infants. Although EELV equals FRC (where the lung and chest wall recoils are equal but opposite in sign, also called equilibrium volume) in a quietly breathing adult, this assumption is not always fulfilled in infants, especially in the presence of lung disease. Therefore EELV may change after the administration of albuterol and the flow-volume curves are obtained on different absolute lung volumes before and after albuterol. Since flow is measured at "FRC," it may appear—misleadingly—that the bronchodilator treatment had no beneficial effect (or even had an inverse effect)[64–66]; however, most probably only the lung volume changed and consequently the maximum flow at FRC decreased. This is a well-documented limitation of the RTC and explains the controversies in the interpretation of BDR when measured with this technique.

Flow-volume curves obtained with the RV-RTC have been shown to be more reproducible and hence more useful in the detection of BDR (Fig. 11.14).[67–69] When the two techniques were compared in the same infants, no changes were detected with RTC in children with acute viral bronchiolitis, while more than half of the children had a positive response to albuterol when assessed with RV-RTC.[67] When changes in individuals were analyzed, $V'_{max,FRC}$ was unchanged or decreased in all of the subjects. The fact that previous studies have reported both positive and negative BDR during infancy precluded the establishment of the optimal response to albuterol that differentiates health and disease with the highest specificity and sensitivity for any of the variables.

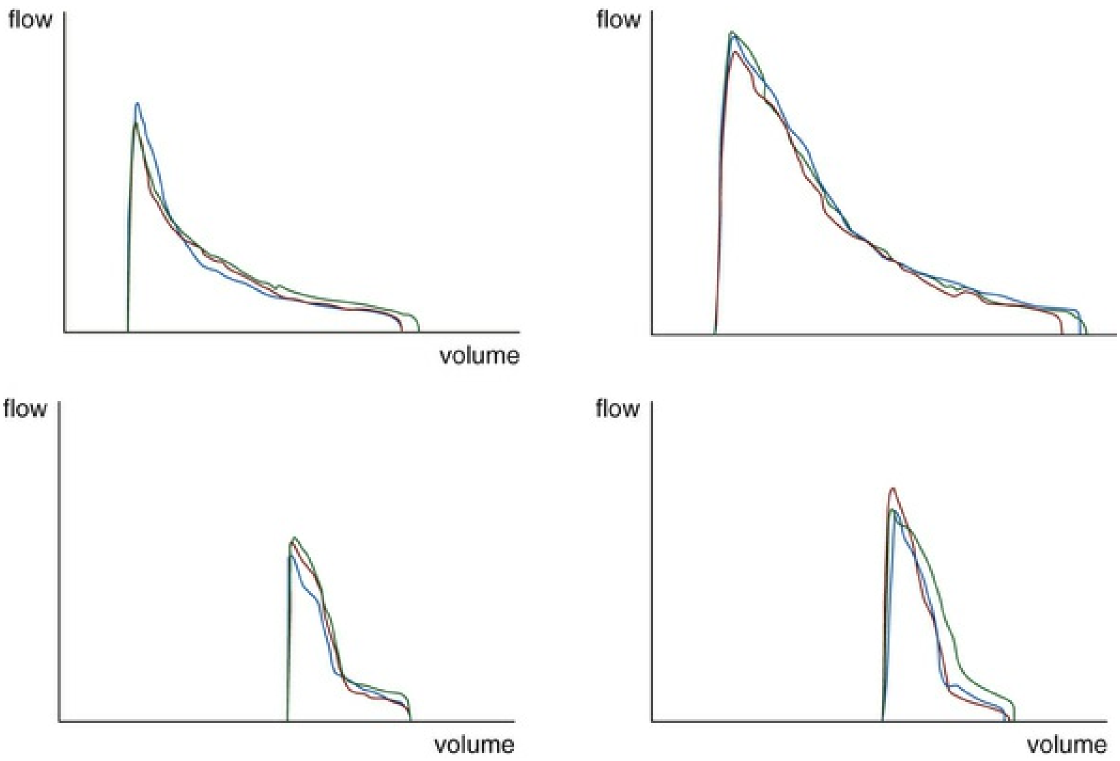

**FIG. 11.14** Changes in the flow-volume curves after the administration of albuterol in infants. Reproducibility: Three prebronchodilator *(left)* and three postbronchodilator *(right)* flow–volume curves from an infant are superimposed for the raised volume rapid thoracoabdominal compression technique *(top)* and for the RTC technique *(bottom).* (Modl M, Eber E, Weinhandl E, et al. Assessment of bronchodilator responsiveness in infants with bronchiolitis. A comparison of the tidal and the raised volume rapid thoracoabdominal compression technique. *Am J Respir Crit Care Med*. 2000;161(3 Pt 1):763-768.)

Positive BDR as assessed with the spirometry is usually defined as ≥12% and/or 200 mL improvement in $FEV_1$ in older children, but this is not appropriate in children younger than 6 years of age. A positive BDR assessed when the child is symptom-free can strengthen the diagnosis of asthma. On the basis of the limited data available in preschool-age children on BDR and spirometry, $FEV_{0.75}$ has been suggested to have the biggest potential to detect positive BDR in children between 3 and 6 years of age.[33,49,70] In a relatively small population of 43 asthmatic and 22 healthy children, 14% improvement in $FEV_{0.75}$ was defined as a positive response.[49] A more recent study on a much larger population of healthy ($n$ = 431) and asthmatic ($n = 289$) children has suggested that 11% increase in $FEV_{0.75}$ was 51% sensitive and 88% specific to detect altered lung function in asthmatic children.[33]

# Measurement of Resistance and Compliance

Resistance and compliance are the most important mechanical properties of the respiratory system. The measurement of respiratory resistance is the most frequently chosen alternative lung function test in clinical practice in preschool-age children who are not able to do spirometry. The resistance of the airways is highly dependent on the airway caliber; therefore the measurement of resistance can be informative in both obstructive and restrictive lung diseases. Resistance describes the relationship between pressure (P) and flow (V′), and combines the determinants of energy dissipation in the airways and the respiratory tissues. Compliance describes the relationship between P and volume (V), and characterizes the ability of the tissues to expand in response to distending pressure and to store elastic energy. Both resistance and compliance depend on (1) the range of deformation of the respiratory system and (2) the rate (frequency) of the deformation. These factors make the comparison of measurements with different techniques difficult.

Several techniques are available for the measurement of resistance and compliance in infants and preschool-age children both during dynamic and quasi-static conditions. Although the techniques differ in their measurement principles and outcome measures, the feasibility in different patient groups, and the level of cooperation required, the main physiological assumptions of the measurement and interpretation of resistance and compliance apply to all of these techniques; therefore they will be discussed together below.

## Physiological Principles and Assumptions

Breathing is accomplished by the rhythmic action of the respiratory muscles, which create forces to overcome the opposing elastic and viscous forces of the lungs and also other structures involved in the respiratory movements, including the muscles themselves. Knowledge on the mechanical properties of the lungs and chest wall is important not only for the assessment of the work needed to maintain breathing but also because significant alterations in elastance and resistance may occur as a result of pathological processes. In infancy and childhood, it is also important to know whether the values of mechanical parameters observed in a subject are in accordance with those predicted for the particular stage of lung development.

The respiratory muscles are responsible for the tidal expansion of a passive system (i.e., lungs and upper airways), and therefore they have to overcome a pressure (the so-called transpulmonary pressure, $P_{tp}$) that arises from the elastic, resistive, and inertial forces of the lungs during tidal breathing. In general, we can describe this pressure as

$$P_{tp} = P_{0,L} + P_{el,L} + P_{res,L} + P_{i,L}$$

where $P_{0,L}$ is a constant corresponding to the recoil pressure in the lungs at the end of expiration (the static balance between the inward recoil of the lungs and outward recoil of the chest wall); $P_{el,L}$ is the pressure required to distend the elastic structures while $P_{res,L}$ is required to overcome the frictional forces of the lungs. Increase in any of these components leads to an elevated $P_{tp}$ and consequently increases the work of breathing, which is one of the most common symptoms of a severe respiratory disorder. $P_{i,L}$ is the pressure necessary to accelerate and decelerate the gas columns in the large airways; while the contribution of $P_{i,L}$ is relatively insignificant during quiet breathing, it can be increased at high breathing frequencies contributing to the elevation of the work of breathing accomplished by the respiratory muscles. The above equation can thus be written as

$$P_{tp} = P_{0,L} + E_L \times V + R_L \times V' + I_L \times V'',$$

where $E_L$, $R_L$, and $I_L$, respectively, denote the elastance, resistance, and inertance of the lungs. We note that, in general, these mechanical parameters are not simple coefficients but are functions of V, V′, and acceleration (V″). For example, $R_L$ depends on the actual lung volume and also the flow itself as airway resistance increases at higher V′ values due to turbulences. Still, the above “equation of motion” of the lungs is often considered as a linear model of pulmonary mechanics.

In the routine clinical practice, $P_{tp}$ cannot be measured easily in children, since it is semi-invasive and requires the placement of a pressure (balloon) transducer in the esophagus. Therefore pulmonary resistance, elastance, and inertance are not calculated directly in children in a clinical setting (except in mechanically ventilated children[71]; however, respiratory mechanics measured in the intensive care unit are out of the scope of this chapter).

When an external driving pressure is applied (e.g., during mechanical ventilation or when forced oscillations are employed to measure respiratory mechanics), the driving pressure that has to overcome the resistive, elastic, and inertial forces of the total respiratory system including the chest wall compartment is higher than $P_{tp}$ and called transrespiratory pressure ($P_{rs}$):

$$P_{rs} = P_{0,rs} + E_{rs} \times V + R_{rs} \times V' + I_{rs} \times V''$$

where $E_{rs}$, $R_{rs}$, and $I_{rs}$ reflect the elastance, resistance, and inertance of both the lungs and the chest wall (Fig. 11.15), respectively, and $P_{0,rs}$ is a constant (e.g., it can be a positive end-expiratory pressure [PEEP] level in mechanical ventilation but in most measurements the setting is zero).

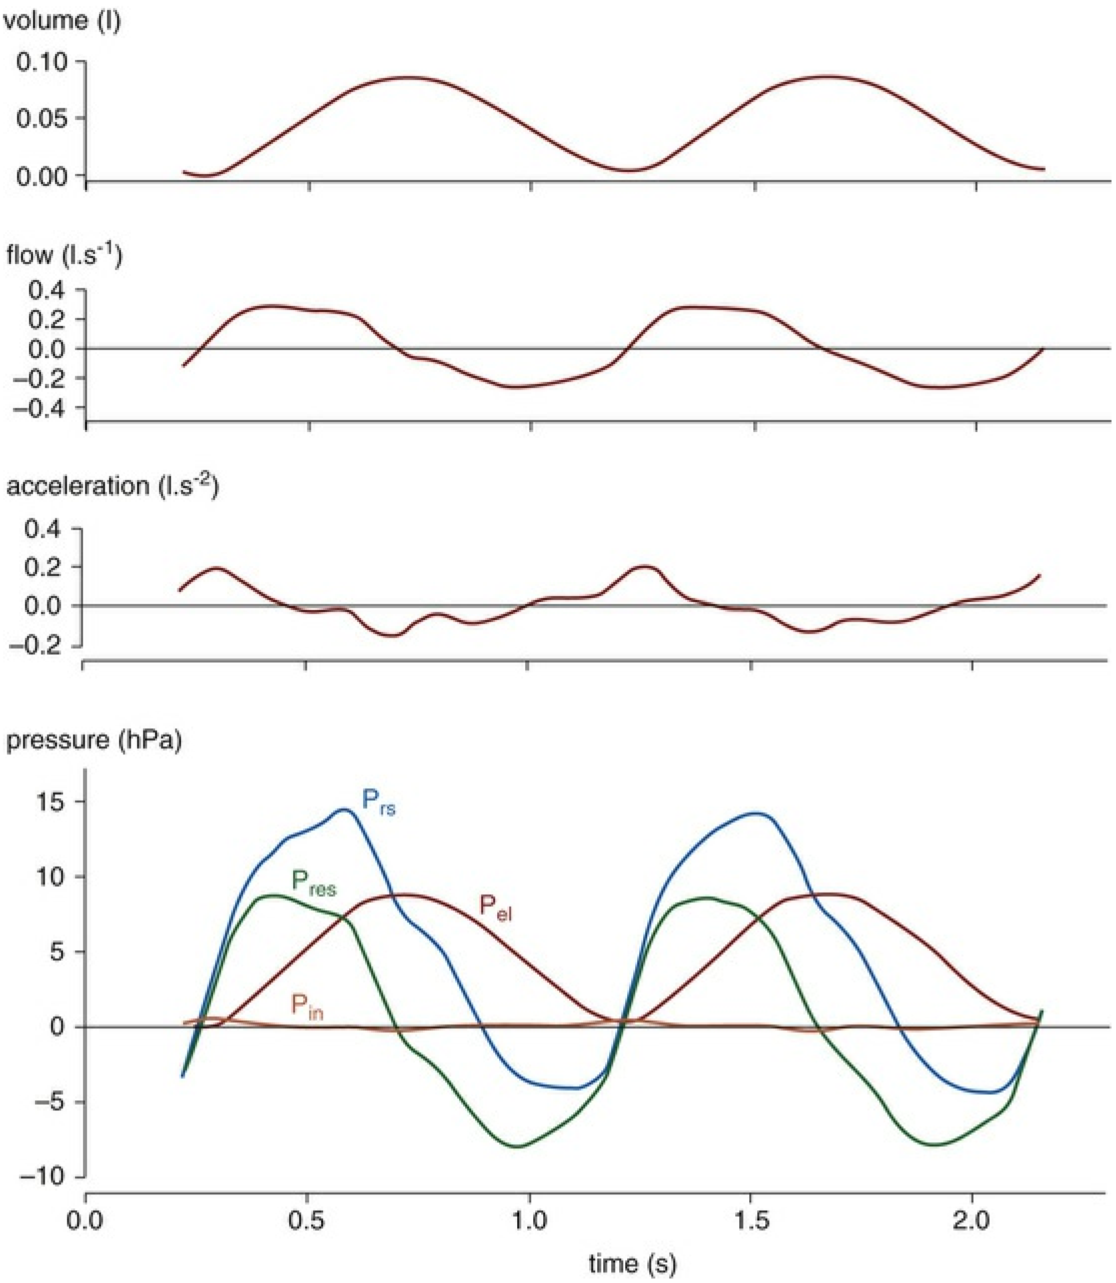

**FIG. 11.15** Equation of motion of the respiratory system. Signals of volume, flow, and acceleration during sleep in an infant, illustrating the general equation of motion of the respiratory system. The pressure necessary to maintain breathing ($P_{rs}$, *black line*) is the sum of elastic ($P_{el}$, *red line*), resistive ($P_{res}$, *blue line*), and inertial ($P_{in}$, *green line*) components, which are proportional to volume, flow, and acceleration, respectively. During tidal breathing the contribution of $P_{in}$ is negligible (even in an infant) and $P_{rs}$ is mainly determined by $P_{el}$ and $P_{res}$.

## Interpretation of Resistance and Compliance

### Summary

- Respiratory resistance and compliance are the most important mechanical properties of the respiratory system, and they describe the relationships between pressure, flow, and volume
- The values of resistance and compliance depend on the measurement method; therefore values obtained with different tests are not directly comparable
- Respiratory resistance ($R_{rs}$) is the sum of the lung resistance ($R_L$) and the resistance of the chest wall ($R_{cw}$). The components of $R_L$ are the airway resistance ($R_{aw}$) and lung tissue resistance ($R_{ti,L}$)
- The relative contribution of the airways, tissue, and chest wall resistance to the total resistance varies with age and between respiratory conditions
- Respiratory compliance is the reciprocal of the respiratory elastance ($E_{rs}$), which is the sum of the lung elastance ($E_L$) and the chest wall elastance ($E_{cw}$)
- $E_{rs}$ is mainly determined by $E_L$ in infants and preschool-age children as the chest wall is much softer than in adults

Total respiratory resistance ($R_{rs}$) is a combination of the resistance of the chest wall and the lungs (including the extrathoracic airways, Fig. 11.16). One of the main components of $R_{rs}$ is the airway resistance ($R_{aw}$), which is the main interest of clinicians, and it is defined as the ratio of the pressure drop across the airway tree ($P_{aw}$) to the resulting airflow (V′):

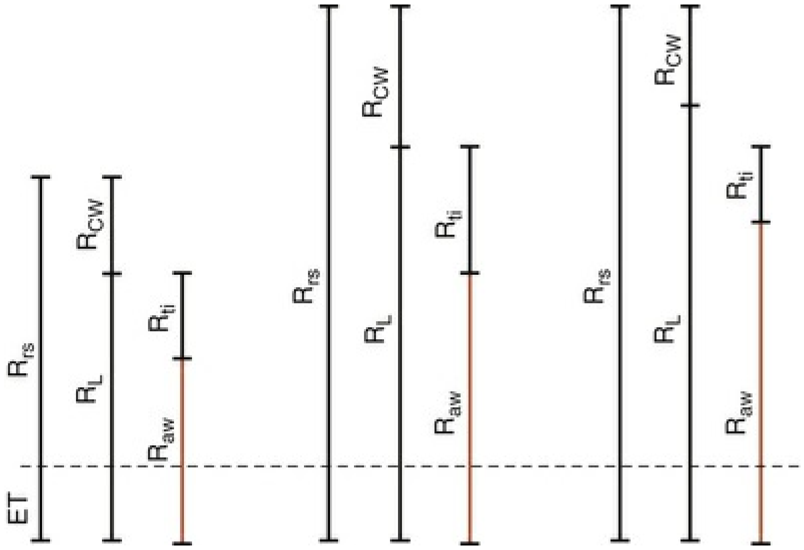

**FIG. 11.16** Schematic contribution of the lung ($R_L$) and chest wall resistance ($R_{cw}$) to the total respiratory system resistance ($R_{rs}$) in health *(left)*, restrictive *(middle)*, and obstructive *(right)* lung disease. Please note that the relative contribution of the extrathoracic airways (ET) is the most significant in healthy subjects. *$R_{aw}$,* Airway resistance; *$R_{ti}$,* tissue resistance.

$$R_{aw} = P_{aw}/V'$$

Ideally, $R_{aw}$ depends only on the geometry of the airway tree and the viscosity of the resident gas. $R_{aw}$ shows a very strong inverse relationship with the airway radius, r ($R \sim 1/r^4$), which (theoretically) means a 16-fold increase in resistance if the airway caliber decreased to 50% of its original value (since the airway tree is a complex system of airways from different sizes with parallel and serial units, this relationship is less straightforward in reality). This is the main reason why the measurement of resistance has become very popular in respiratory disorders that are likely to affect the airway caliber (e.g., asthma, CF).

However, it is known that the irregular geometry of the airways and high flows lead to the development of turbulence where $P_{aw}$ increases faster than V′, and the ideal proportionality between $P_{aw}$ and V′ changes and the above equation is not true anymore. Turbulence develops typically in the upper airways because of the sudden changes in the cross-sectional area, such as in the nasal pathway and the glottic area. Additionally, via the changes in the bronchial diameter, $R_{aw}$ exhibits a marked inverse relationship with lung volume. $R_{aw}$ can only be measured noninvasively with the plethysmographic technique in both infants and young children in whom the alveolar pressure can be estimated from the volume changes within the box (see details below). Since FRC is hardly ever measured in preschool-age children (see also in the *Measurement of Lung Volumes* part of this chapter), $sR_{aw}$ (specific $R_{aw}$, which is the product of $R_{aw}$ and FRC, without directly measuring either of these variables) can be obtained. The details of the measurement and its limitations are discussed below.

Tissue resistance ($R_{ti}$) is another significant contributor to $R_{rs}$; however, its description in terms of classical mechanics is limited.[72] As recent research has shown, $R_{ti}$ is closely linked to the elastic behavior of the tissues, in the sense that the ratio of the energy dissipated and stored in the tissues during a breathing movement (i.e., the tissue hysteresivity) is fairly constant.[73,74] This is a general and fundamental property of the tissues, with the implication that $R_{ti}$ decreases, roughly inversely, with increasing respiratory rate or external oscillation frequency, that is, in the same way as the elastic forces diminish. From a practical point, this means that while $R_{aw}$ is nearly constant at breathing rates and up to 10–20 Hz of external oscillations, $R_{ti}$ contributes equally to $R_{rs}$ during spontaneous breathing but rapidly disappears above 3–5 Hz (Fig. 11.17; see also below in the discussion of *Forced Oscillation Technique*). This fact has often been overlooked both when interpreting $R_{rs}$ obtained with different techniques as a measure of airway resistance and assuming $R_{ti}$ as a constant, frequency-independent resistance. $R_{rs}$ can be obtained from the measurement of respiratory impedance ($Z_{rs}$) with the forced oscillation technique (FOT) and with the single-breath occlusion technique (SOT); while the FOT employs oscillation frequencies well above the tidal breathing rate (>4 Hz), the latter estimates $R_{rs}$ over a passive expiration from end-inspiration; therefore the contribution of $R_{ti}$ to $R_{rs}$ is more significant when measured with the SOT. Resistance values obtained with the interrupter technique ($R_{int}$) are also influenced by the tissues as a result of the involvement of the stress relaxation in the measurement of airway-opening pressure (see below).

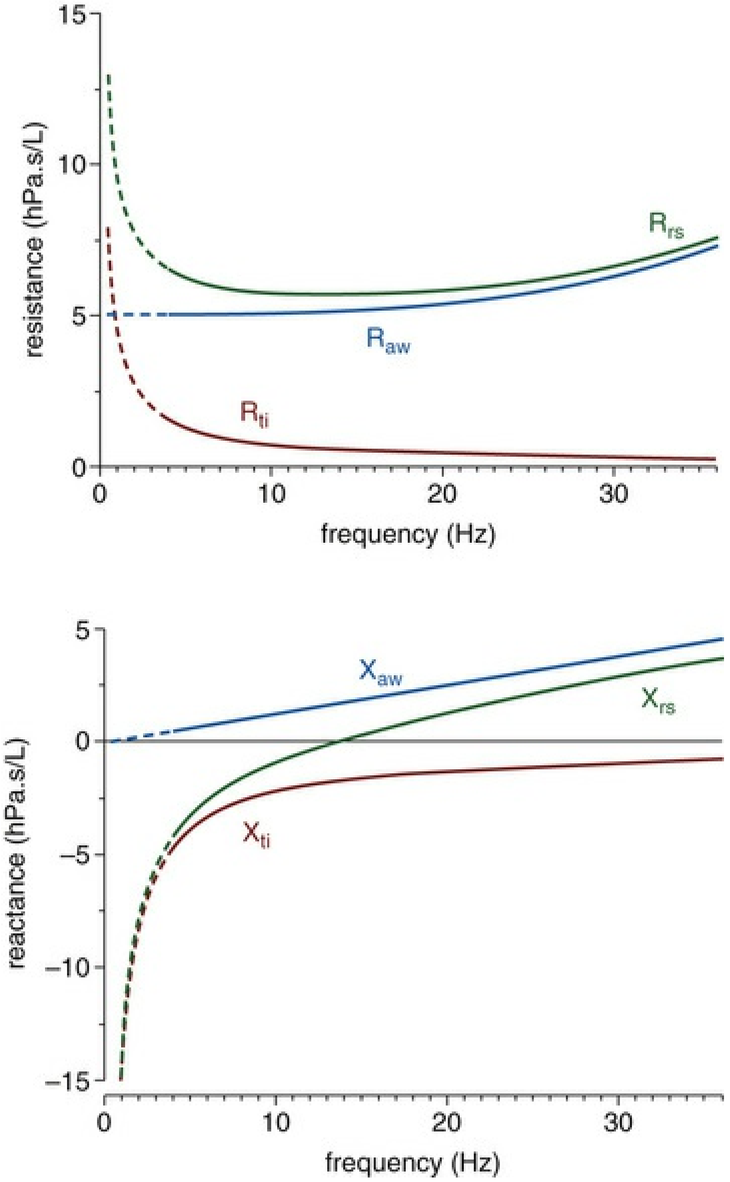

**FIG. 11.17** Illustration of the frequency dependence of total respiratory resistance ($R_{rs}$, *top*) and reactance ($X_{rs}$, *bottom*), and their corresponding components

from the airways (aw) and respiratory tissues (ti). Solid lines depict the frequency interval of impedance available from measurements during normal breathing; broken lines indicate the courses of low-frequency impedance measurable only during apnea. Note the zero-crossing of $X_{rs}$ (the resonant frequency) where the elastic and inertial forces are equal in magnitude.

Elastance (E) expresses the relationship between changes in distending pressure ($\Delta P_{el}$) and the corresponding volume ($\Delta V$) as

$$E = \Delta P_{el}/\Delta V$$

E is the reciprocal of compliance ($C = 1/E = \Delta V/\Delta P_{el}$), which is perhaps more commonly reported to characterize the elastic properties of the respiratory system. The elastance of the total respiratory system, $E_{rs}$ is the sum of that of the pulmonary (L) and chest wall (cw) components (Fig. 11.18):

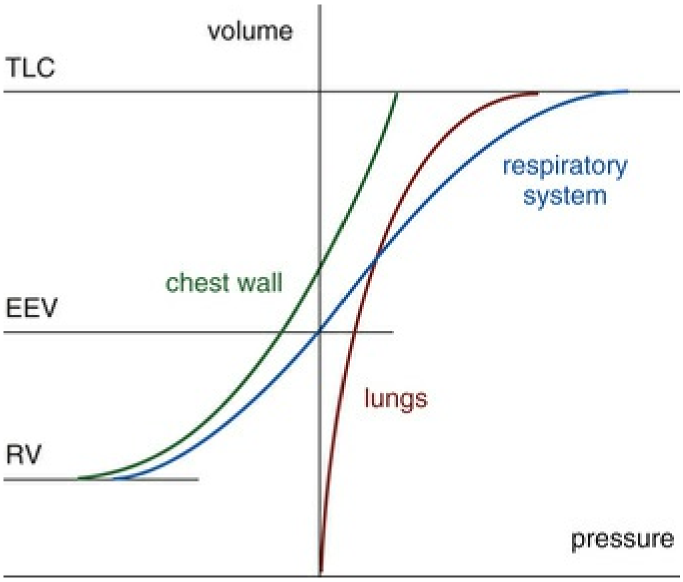

**FIG. 11.18** The pressure-volume relationship of the respiratory system as added up by the pulmonary and chest wall components. Note the decrease in slope at low volumes (near residual volume, RV) and high volumes (approaching total lung capacity, TLC) caused by the nonlinearity of the chest wall and the lungs, respectively. The highest slope (maximal compliance)

is observed in the normal breathing range, that is, just above elastic equilibrium volume (EEV).

$$E_{rs} = E_L + E_{cw} = (1/C_L) + (1/C_{cw})$$

In newborns and infants who have very compliant chest wall structures, $E_{rs}$ is practically determined by the lungs, whereas it is nearly equally contributed by the pulmonary and chest wall compartments at adulthood. Similarly to the resistances, the values of E vary with lung volume: $E_L$ is the lowest when measured at medium lung volumes (i.e., between FRC and FRC+VT) and increases both toward RV and TLC, whereas $E_{cw}$ increases only at low lung volumes (Figs. 11.18 and 11.19). The volume dependences of each compartment have more or less known structural determinants. The stiffening of the lungs at high volumes is due to the recruitment of the collagen fibers in the parenchymal matrix, whereas at low lung volumes the alveolar configuration and surfactant distribution become suboptimal. The increasing stiffness of the chest wall at low volumes is primarily the consequence of the restriction of the rib cage. Therefore values of E or C are dependent on the level(s) of inflation of the respiratory system, at which the measurements are made. Of course, the measure most relevant to normal breathing is the reading of $\Delta P_{el}$ and $\Delta V$ between the endpoints of tidal breathing, that is, the FRC and FRC+$V_T$; these estimations utilize two points on the nonlinear P-V curve (see Fig. 11.19) and are denoted “chord” compliance ($C_{chord}$) or elastance ($E_{chord}$). Estimation of $C_{chord}$ is either confined to the lungs and requires measurement of esophageal pressure or it is estimated for the total respiratory system during mechanical ventilation, an application outside the scope of the present chapter. Nevertheless, the value of C derived from the SOT measurements (see below) is also based on two-point readings and can be considered as a chord estimate.

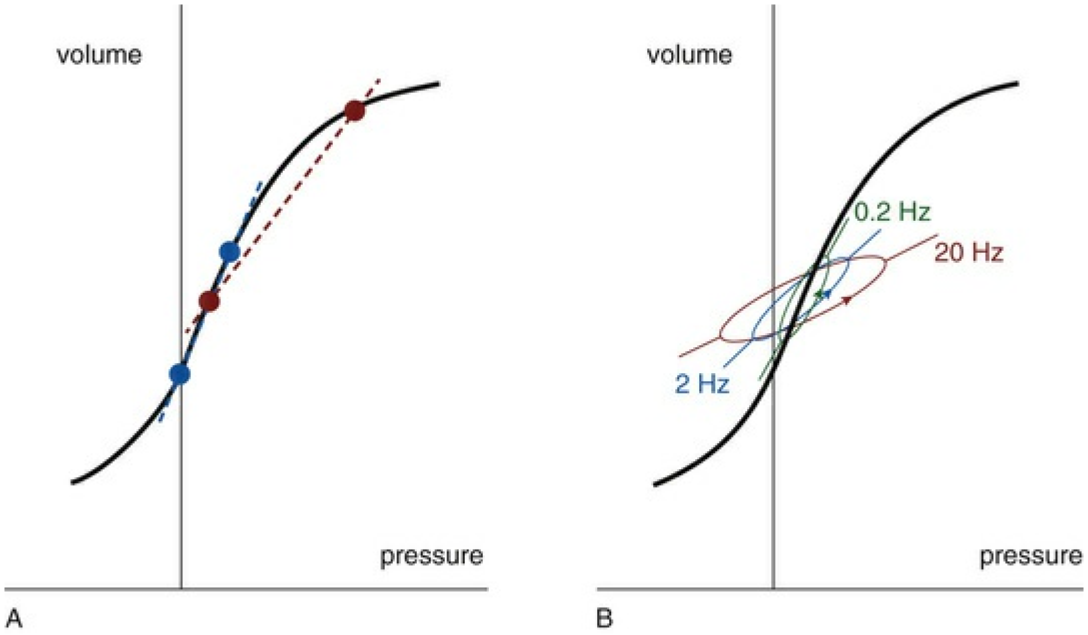

**FIG. 11.19** Estimation of chord compliance. (A) Effect of the nonlinearity of the pressure-volume curve of the respiratory system on the estimation of chord compliance. The highest compliance is obtained in the tidal breathing range (slope between *blue symbols*); at higher volume levels *(red symbols)* compliance is reduced significantly (slope between *red symbols*). (B) Frequency dependence of dynamic compliance. From slow breathing *(green loop)* through panting *(blue loop)* to fast external oscillation *(red loop)* dynamic compliance falls steeply because of lung tissue viscoelasticity.

Similarly to the resistance measures, the estimates of compliance are also dependent on the rate of changes in the respiratory system. The term "static compliance" ($C_{st}$) is commonly associated with any change that is slower than the normal breathing and is therefore often misused. The only correct use of $C_{st}$ is in connection with the weighted spirometer technique, where added weights to the bell of a closed spirometer result in stepwise changes in $P_{rs}$ and lung volume, and these steps can last for minutes and cover many breaths. Compliance values based on the SOT are determined from a passive expiration to atmospheric pressure following an end-inspiratory airway occlusion. The readings of P and V are taken at both ends of the (relaxed) expiration and are just a fragment of a second apart; accordingly, they reflect the compliant behavior on a much shorter time scale. Finally, the FOT measurements that cover the frequency range from a few Hz to 40–50 Hz reveal the combined effects of elasticity of the tissues and the inertial behavior of the large airways, the former dominating at the lower frequencies and the latter being the main determinant above the resonance frequency (see Fig. 11.17). As a result of the dependence of the elastic properties on frequency, the compliance determined by the FOT is ~5–10 times lower than that observed at the breathing frequency, and the difference is further increased in the comparison with $C_{st}$ values. In the low-frequency implementation of FOT (LFOT), frequencies as low as 0.5–1 Hz are employed during apneic intervals,[75] the compliance values derived from the impedance spectra represent more the dynamic compliance relevant to spontaneous breathing. The frequency dependence of C, that is, the decrease in C with frequency is augmented in the case of inhomogeneous obstruction of the lungs.[76]

In summary, it is important to emphasize that the measures of both resistance and compliance are fundamentally determined by the measurement technique because of the two main underlying properties of respiratory mechanics: the nonlinearity and the frequency dependence. *Nonlinearity* means that higher flows increase resistance because of changes in the airway flow profile and the development of turbulent flow (especially in the central airways). A particularly serious form of nonlinear behavior is the flow limitation, which may occur during tidal breathing in collapsible segments of the airway tree. In the context of the elastic properties of the respiratory system, nonlinearity refers to the value of compliance depending on the working point or segment of the pressure-volume curve where it is measured: the “best” compliance is measured in the range of normal tidal breathing and the respiratory system becomes stiffer towards both large and low lung volumes. *Frequency dependence* is a property that applies to both resistance and compliance

## General Considerations for the Measurement of Resistance and Compliance

The measurements of respiratory resistance and compliance are usually performed during tidal breathing. In both infants and children the upper airways should always be free and open; therefore the position of the child needs to be checked carefully during the test. When the measurement is done via a mouthpiece in children, the cheeks and the floor of the mouth are supported firmly to minimize the upper airway shunt. To avoid nasal breathing, a nose clip must be worn during the test (Fig. 11.20).

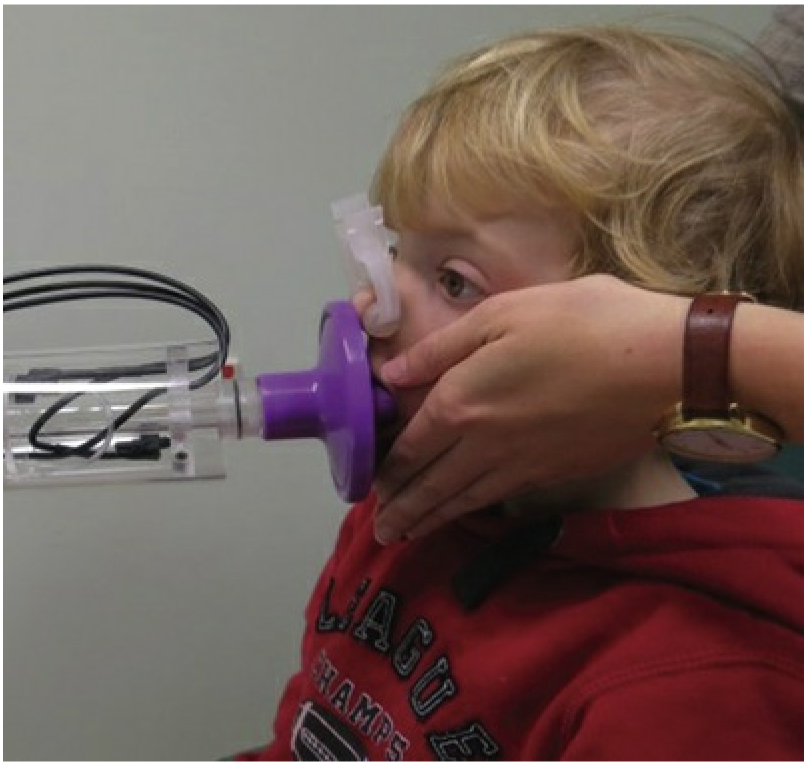

**FIG. 11.20** Measurement of respiratory resistance and compliance with a forced oscillation technique in a 3-year-old child. Nose clip is worn during the test and cheeks are also firmly supported by a staff member.

The main limitation of the measurement of resistance in spontaneously breathing children and adults is the involvement of the upper airways (i.e., extrathoracic airways), which makes it nearly impossible to assess the intrathoracic airways objectively. Furthermore, the breathing pattern is naturally variable in children (e.g., unstable FRC, frequent expiratory braking, etc.), which can increase the values of resistance even in healthy children. These factors contribute to the wide range of reference data for a given height in healthy preschool-age children (Fig. 11.21) resulting in a limited clinical utility of respiratory resistance in individuals (see also below).

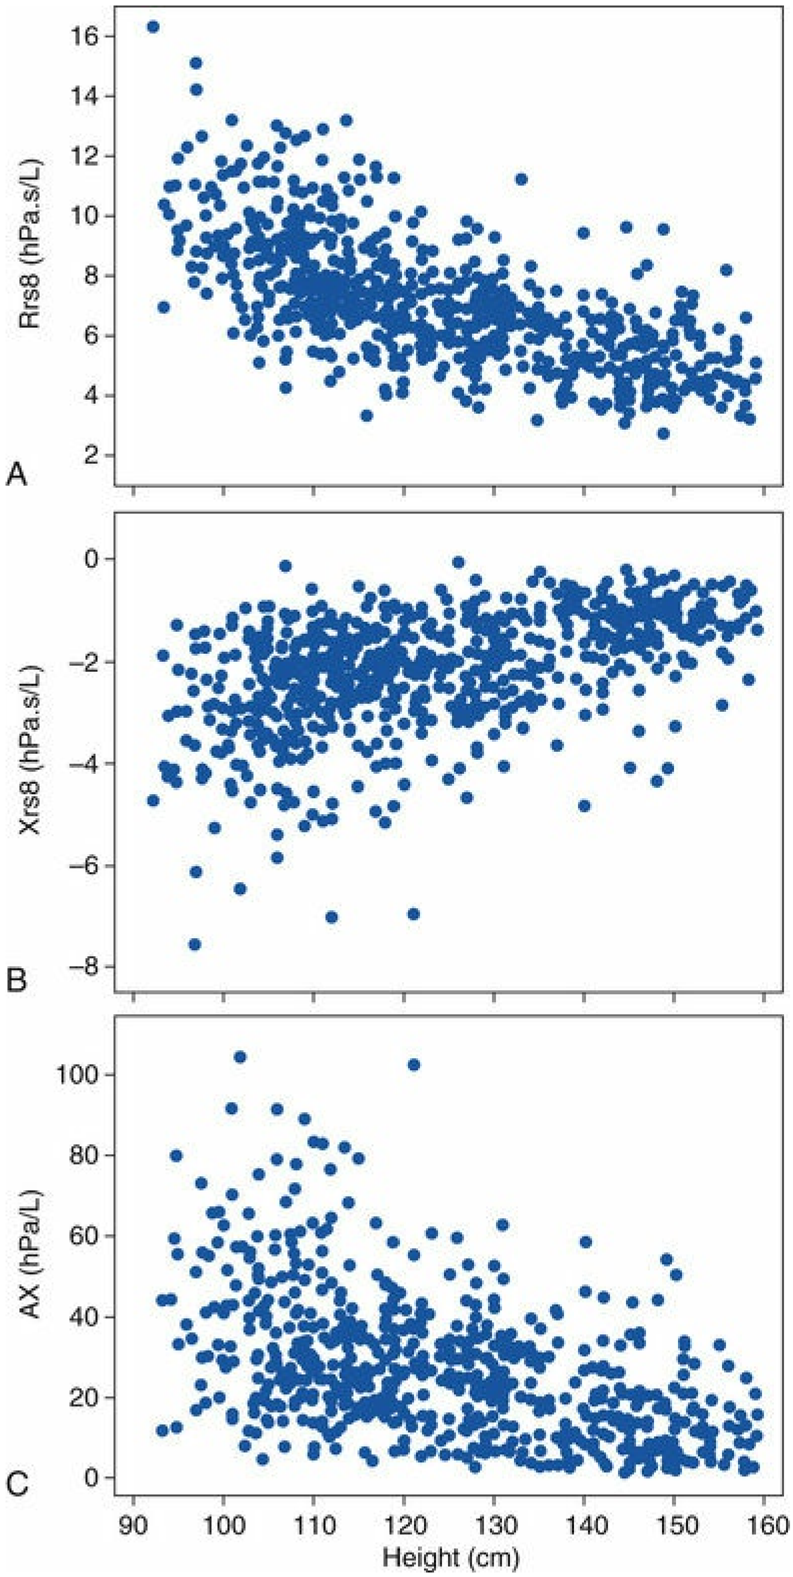

**FIG. 11.21** Baseline respiratory resistance at 8 Hz (Rrs8) (A), reactance at 8 Hz (Xrs8) (B), and area

under the reactance curve (AX) between 6 Hz and the resonant frequency (C) against height in healthy children measured in two centers in Australia and Italy. Note the wide range of reference values for a given height. (Calogero C, Simpson SJ, Lombardi E, et al. Respiratory impedance and bronchodilator responsiveness in healthy children aged 2-13 years. *Pediatr Pulmonol*. 2013;48(7):707-715.)

The involvement of the upper airways and their contribution to the total resistance is even more significant in infants who are preferential nasal breathers. The narrow nasal pathways are responsible for as much as 25%–50% of the respiratory resistance[77,78] and this significant contribution of the upper airways might mask small alterations within the lungs.

## Single-Breath Occlusion Technique

The SOT has become one of the most popular infant lung function tests, as it is commercially available, relatively easy to use and provides robust estimates of the total respiratory resistance and compliance. Reference values are available for different populations, and guidelines have also been published, which can help an inexperienced user to establish the test for both research and clinical studies.

### Summary

- Commercial devices and reference values are available
- In infants, interruption of spontaneous breathing evokes reflex relaxation of respiratory muscles
- Compliance of the respiratory system ($C_{rs}$) is estimated from occlusion pressure and the passively expired volume recorded subsequently
- Flow-volume relationship during relaxed expiration yields the time constant of the total

respiratory system ($\tau_{rs}$) to enable estimation of the resistance as $R_{rs} = \tau_{rs}/C_{rs}$

- Limitations in airway obstruction and where full relaxation is not achieved

The SOT offers a simultaneous assessment of the resistance and compliance of the *passive* respiratory system during interruption of spontaneous breathing in the expiratory phase. In infants, the occlusion evokes the Hering-Breuer lung inflation reflex via mediation of stretch receptors (see also *Lung function in Sedated Infants*, earlier in this chapter), which inhibits inspiratory effort and leads to an apnea and, following the release of occlusion, a passive expiration. While the apneic condition is difficult to achieve in adults and older children, the Hering-Breuer lung inflation reflex can be evoked in neonates and infants for the measurement of lung function with the SOT[79] or LFOT (see below).[75] The duration of the reflex relaxation of the respiratory muscles decreases with age; however, it can still be evoked during sedation in young children.[80]

During the measurement procedure, tidal breathing is recorded with a flow meter through the facemask for at least 30 seconds or until a stable breathing pattern is achieved. Interruption is accomplished with closing a valve at the airway opening, usually at end inspiration or at various phases of expiration. If the Hering-Breuer reflex is active, the respiratory system relaxes against the valve and the developing increase in airway-opening pressure ($\Delta P_{ao}$) will represent the change in the elastic pressure belonging to the volume change ($\Delta V$) above the relaxation volume ($V_r$) (Fig. 11.22). During the occlusion, the equilibration of $P_{ao}$ to the alveolar pressure is indicated by a plateau in $P_{ao}$ (we note here that the pressure equilibrium cannot always be achieved in the presence of airway obstruction; see details below). The occlusion is released after a 100-ms plateau, and a flowmeter records the expired volume ($\Delta V$) reached until the next uninterrupted inspiration (see Fig. 11.22). The compliance of the total respiratory system ($C_{rs}$) is estimated as[81]:

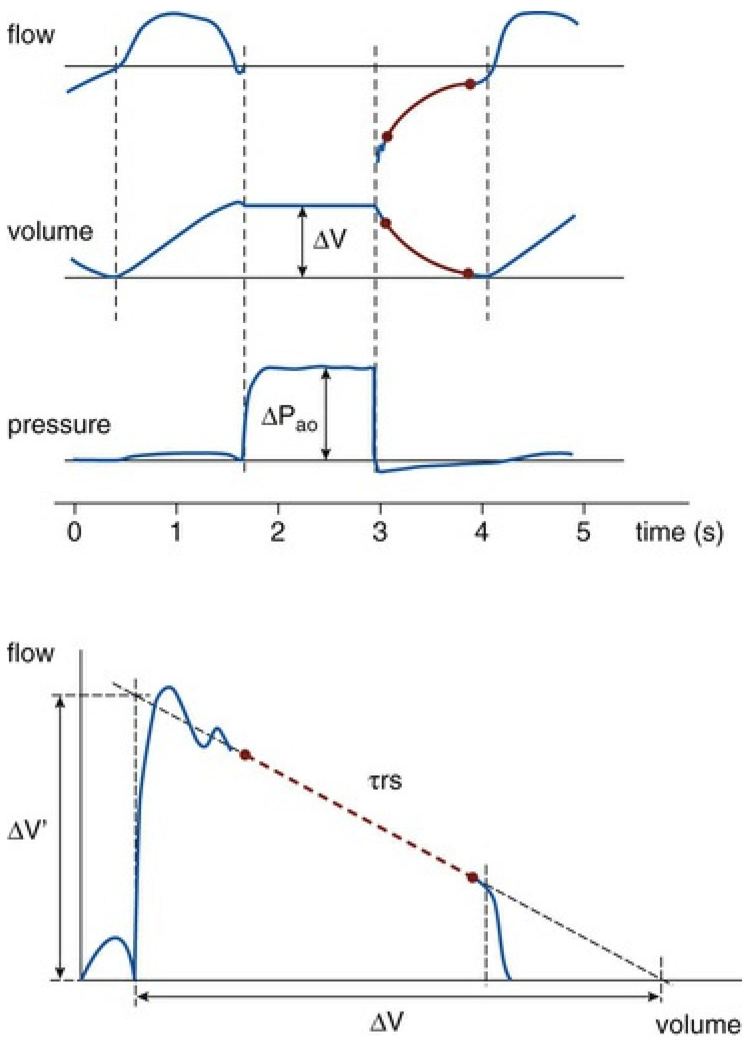

**FIG. 11.22** Schematics of the single-breath occlusion measurement (SOT). Top: The airway is occluded at end inspiration, evoking the Hering-Breuer reflex apnea. From the developing airway-opening pressure ($\Delta P_{ao}$) and the volume exhaled in the subsequent relaxed expiration (ΔV), the total respiratory compliance ($C_{rs}$) is calculated. Bottom: In the middle of the expiration phase (between the blue dots), the flow-volume relationship is closely linear, and the slope ΔV/ΔV′ gives the time constant of the respiratory system (τrs). Respiratory resistance ($R_{rs}$) is then calculated as ($R_{rs} = \tau rs/C_{rs}$).

$$C_{rs} = \Delta V/\Delta P_{ao}$$

From the same occlusion-reopening maneuver, an estimate of the resistance of the total respiratory system ($R_{rs}$), that is, the sum of airway and tissue resistances, can also be obtained. From the linear part of the V′ versus V relationship (see Fig. 11.22), the time constant ($\tau_{rs}$) of the respiratory system can be obtained during a passive expiration. The $\tau_{rs}$ is by definition the time that required for the lung volume to decrease passively by 63% in an exponential manner. The time of this decrease will depend on the mechanics of the respiratory system, that is, $R_{rs}$ and $C_{rs}$ the following way:

$$\tau_{rs} = R_{rs} \times C_{rs}$$

Therefore $R_{rs}$ can be calculated from the estimates of $C_{rs}$ and $\tau_{rs}$. Normally, three time constants are required to empty 95% of the inspired volume. If the time constant is increased (e.g., because of high resistance), the lungs cannot empty adequately during tidal breathing (especially when the breathing frequency is increased), which results in hyperinflation of the lungs. In contrast, if the time constant is shorter (e.g., because of low compliance), atelectasis can occur during tidal breathing. This latter can often be seen in preterm babies with BPD or respiratory distress syndrome.

Since in neonates and young infants FRC is maintained actively above $V_r$, a single reading of $\Delta V/\Delta P_{ao}$ can lead to underestimations of $C_{rs}$,[82] and this error will in turn lead to false high values of $R_{rs}$ calculated using the same $\tau_{rs}$. Occlusions performed in separate breaths at different phases of expiration (multiple occlusion technique: MOT) provide a set of $\Delta V/\Delta P_{ao}$ values, and regression on these points establishes a more correct estimate of $C_{rs}$.

## Quality Control, Acceptability Criteria, and Limitations

Similarly to all the other infant lung function tests, the most common failure of the measurement is a leak around the facemask. The leak can be recognized by a continuing slow decay in $P_{ao}$ (while a sudden decrease in $P_{ao}$ more likely indicates inspiratory muscle activity). Therefore V, V′, and $P_{ao}$ should be continuously monitored throughout the test and the V′ versus V curves should be displayed real time for quality control purposes.

The test requires a stable EEL, which can be difficult to achieve in young infants (especially when unsedated). Before each occlusion at least 5 breaths should be recorded for the calculation of EEL. Similarly, following the occlusion, EEL should be calculated as an average of 3–4 normal breathing cycles (this might take time after the occlusion; therefore the first few breaths right after the opening of the valve should be excluded from such calculation). The occlusion maneuver is valid if the preocclusion and postocclusion EEL values do not differ more than 1 mL/kg. $C_{rs}$ and $R_{rs}$ are calculated from at least 5 occlusion maneuvers where EEL remains stable and the expiration is artifact-free and passive.

The key assumption underlying the use of the SOT is the passive behavior of the respiratory system, both in the occlusion phase and the subsequent expiration. The absence of muscle activity during occlusion is substantiated by a stable plateau in $P_{ao}$ and a stable linear segment in the V′ versus V relationship during the expiration (at least 40% of the total expiration, see Fig. 11.22). A late rise in $P_{ao}$ in the plateau phase marks the onset of expiratory muscle activity, which means that while the $\Delta V/\Delta P_{ao}$ can still be read, the postocclusion decay will not be passive.

The absence of the artefacts discussed above does not automatically mean that the $C_{rs}$ and $R_{rs}$ readings are correct. In the presence of peripheral lung inhomogeneity, the time of occlusion might be insufficient for $P_{ao}$ to equilibrate fully to a uniform alveolar pressure (i.e., elastic recoil pressure), which will lead to an underestimation of the alveolar pressure. It also needs to be stressed that the SOT and MOT methods rely on simple biomechanical assumptions. While $C_{rs}$ can be taken as a constant in healthy infants within a tidal range above $V_r$, the postocclusion relaxed expiration may not follow a strictly exponential decay if $R_{rs}$ is not constant during the tidal expiration. Departure from a constant $R_{rs}$ may occur in the case of marked pressure-flow nonlinearities in the upper airways, and because the stress relaxation/recovery processes in the living tissues do not follow the monoexponential decay either.

### Potential Clinical Applications in Infants

With the above-mentioned methodological limitations kept in mind, the SOT can be employed as a relatively simple and informative technique on the respiratory mechanical status in infancy. $C_{rs}$ is primarily associated with lung size and is an indicator of lung development, while $R_{rs}$ is greatly influenced by the narrow upper airways when measured through a facemask. Even with this limitation, $R_{rs}$ has been shown to be elevated in wheezing infants[83] and associated with respiratory symptoms during human rhinovirus infection[84] while exhibiting no relationship with respiratory problems later in life. $R_{rs}$ was also increased in late preterms compared to term infants.[85,86]

Low $C_{rs}$ at birth was shown to predict wheeze during the first 5 years of life[83] and related to the development of asthma later in life.[83,87] Infants with BPD have reduced $C_{rs}$ values[88]; however, the interpretation of low $C_{rs}$ values in small infants warrants caution. It has been reported that somatic growth is a very strong confounding factor in $C_{rs}$[86]; therefore the normalization of the $C_{rs}$ measures to body size is recommended. This also explains the importance of the measurement of FRC in the interpretation of respiratory mechanics.

## Measurement of Interrupter Resistance

The measurement of the respiratory resistance during a short interruption of the tidal flow was first described in the late 1920s. Nowadays, commercial devices and age-specific recommendations are available and healthy reference values with *z*-scores have also been established.[89] The technique is highly feasible in young children (similarly to the FOT and $sR_{aw}$ test) as it only requires tidal breathing; therefore it is easy and quick to perform. Since portable devices are also available, it can also be employed in field work.

### Summary

- Measurement of interrupter resistance ($R_{int}$) during tidal breathing via short occlusions of the

flow either during inspiration or expiration
- Highly feasible in children
- $R_{int}$ is calculated from the mouth pressure during the interruption and the flow right before the interruption
- Reference values for both inspiratory and expiratory $R_{int}$ values, commercial devices, and recommendations are available
- Main limitation is the underestimation of airway resistance in the presence of severe airway obstruction

It was first described in 1927 that if at any point of the breathing cycle the airway opening is briefly occluded, then V′ falls immediately to zero while the $P_{ao}$ rapidly increases to a new level during the occlusion.[90] It has also been established that the magnitude of this rapid pressure change depends on the difference between the alveolar and mouth pressure immediately before the occlusion. These findings have led to the development of a lung function technique that is highly feasible in spontaneously breathing young children and provides an estimate of resistance.

The principle of the technique is a brief occlusion of the tidal flow (usually peak flow) that is not recognizable by the child (~100 ms), but sufficient enough to reach equilibrium between the mouth pressure ($P_{mo}$) and the alveolar pressure. The interrupter resistance ($R_{int}$) is then calculated as

$$R_{int} = P_{mo}/V'$$

where $P_{mo}$ is the mouth pressure during the occlusion while V′ is the tidal flow measured before the occlusion. During the short occlusion, the plateau that indicates the equilibrium is reached in a typical manner (Fig. 11.23). First, $P_{mo}$ is immediately and rapidly increasing as a result of the pressure difference due to the airway resistance at the time of the occlusion ($P_{init}$). In reality, this rapid change is not constant and involves several rapid oscillations due to the air movement in the respiratory system (see Fig. 11.23). This makes the measurement of $P_{init}$ technically challenging. This short initial phase of rapid increase is followed by a slow elevation in the pressure that reflects the stress adaptation of the viscoelastic tissue and the gas redistribution between the peripheral lung units (this phenomenon of the gas movement between parallel units of the lung is called *pendelluft*). The third phase of the pressure change following the occlusion is a plateau of the pressure, which represents the elastic recoil pressure of the respiratory system. Various methods have been suggested to calculate the fast initial resistive pressure drop (i.e., $P_{init}$). The most commonly applied method is the linear back-extrapolation of the pressure by using the two-point method: $P_{mo}$ at 70 ms and 30 ms to either 15 ms or 0 ms after the interruption (see Fig. 11.23). This means that the obtained value of $P_{init}$ is not only dependent on the resistive pressure drop but is also influenced by the viscoelastic properties of the respiratory system (i.e., $R_{int}$ does not equal to $R_{aw}$).

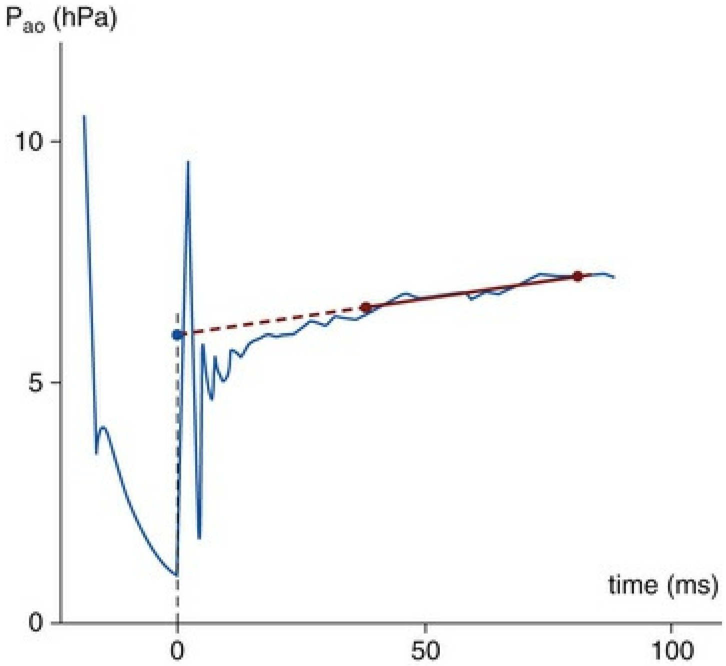

**FIG. 11.23** Measurement of the airway-opening

pressure ($P_{ao}$) with the interrupter technique. Following the brief occlusion (0 ms), $P_{ao}$ is rapidly increasing with characteristic oscillations (see the text for details). The initial pressure that represents all the Newtonian resistive pressure in the respiratory system is obtained with linear back-extrapolation *(solid and dashed red line)* between 30 and 70 ms *(red symbols)* to 0 ms *(blue symbol).*

In the commercial devices, the occlusion is automatically triggered usually at either the inspiratory or expiratory peak flow. Findings on expiratory and inspiratory $R_{int}$ values in preschool-age children are inconsistent, as some studies reported higher $R_{int}$ during expiration[91,92] while others have found no difference.[89,93,94] Nevertheless, the timing of the occlusion always has to be reported and comparisons with data collected in other centers should always be made carefully.

## Quality Control, Acceptability Criteria, and Limitations

For an acceptable $R_{int}$ test, a minimum of 5–10 interruptions should be made and the average of at least 5 technically acceptable measurements is reported. A measurement is considered technically acceptable if there is no leak around the mouthpiece (as indicated by the decrease in $P_{mo}$ following the initial rapid increase) and there are no obvious artefacts such as vocalization, coughing, or swallowing. Although the brief occlusion is not recognizable by the patient, the fast closing of the shutter makes a noise, which can disturb the child. Time should be allowed for the child to become familiar with the device and the measurement method.

Similarly to the plethysmography and the SOT, the main limitation of the $R_{int}$ technique is related to moderate or severe airway obstruction and inhomogeneity in the lung periphery. If heterogeneity is present, the equilibrium might not be achieved during the interruption; therefore $P_{init}$ is underestimated. The effect of the cheek support has also been investigated, and there was no difference between $R_{int}$ values measured in the same children with and without the cheek support.[89,94] However, these studies only included healthy children in whom the compliant upper airways are not expected to have a huge influence on the equilibration between the mouth and the alveolar pressures. This may not be the case in the presence of severe airway obstruction, as upper airway shunting can delay pressure equilibration significantly; therefore it is highly recommended to apply cheek support during the measurement of $R_{int}$ in young children.

The clinical usefulness of $R_{int}$ has been investigated in asthmatic children at both baseline and following bronchodilators.[94a,95–97] A decrease of 35% in $R_{int}$ was defined as clinically significant,[96,97] and this cut-off was also validated against spirometry in young children.[98] $R_{int}$ has also been suggested as a potential outcome measure for a clinical trial in young asthmatic children.[99] Findings on $R_{int}$ in CF are controversial.[100–102] Recently, $R_{int}$ was suggested as a feasible measure of diminished lung function in pre-term infants compared to those born term[102a]; however, this technique in infants needs more research.

## Plethysmographic Measurement of Airway Resistance

### Summary

- $R_{aw}$ in older children and adults is measured during a two-step procedure and calculated from the FRC and specific $R_{aw}$ ($sR_{aw} = FRC \times R_{aw}$)
- In young children, FRC cannot be measured reliably; therefore $sR_{aw}$ reflects $R_{aw}$ at a given FRC without actually knowing either $R_{aw}$ or FRC
- Since the technique has been adopted for young children (i.e., special mouthpiece, the possible presence of an adult in the box, etc.) it has become highly feasible in preschool-age children
- Commercial devices, healthy reference data, and

measurement guidelines are available

- Changes in $sR_{aw}$ values can reflect changes in $R_{aw}$ or FRC or both—this remains the main limitation of the technique

Airway resistance has a strong inverse relationship with lung volume; therefore knowledge of the FRC is very useful in the interpretation of $R_{aw}$. The product of FRC and $R_{aw}$ is called specific airway resistance ($sR_{aw}$), which can be measured with the plethysmographic technique in young children.[103] During growth, FRC is increasing while $R_{aw}$ is decreasing; therefore $sR_{aw}$ remains relatively constant during early life and its value is more or less independent of height, weight, and sex. The classical measurement of $R_{aw}$ with the plethysmographic method requires two steps in older children and adults: (1) the measurement of FRC during brief occlusions, and (2) the measurement of $sR_{aw}$. $R_{aw}$ is then calculated as $sR_{aw}$/FRC. The reliable measurement of FRC is very difficult in young children (see also in the *Measurement of Lung Volume* part of this chapter); therefore $sR_{aw}$ can be obtained without actually knowing $R_{aw}$ and FRC separately. An abnormal $sR_{aw}$ can therefore be a consequence of changes either in FRC or $R_{aw}$ (or both) and its value cannot tell which one of these components is abnormal. This remains one of the main limitations of the technique in preschool-age children. $R_{aw}$ is only sporadically reported in children and it is far less frequently used in older children than $sR_{aw}$. Although the measurement is also possible in infants, there are numerous technical limitations, and the interpretation of $sR_{aw}$ data in nasally breathing infants remains unclear. These are the main reasons why this method has not been used frequently in infants and its application is limited to a few centers worldwide. Therefore we will limit our discussion to the measurement of $sR_{aw}$ in children.

Before the measurement, every detail of the procedure should be explained to the child to avoid any unexpected stress and discomfort during the test. Once the child is seated into the plethysmograph chamber, the door should be closed for at least 1 minute before the first measurement to minimize the thermal drift. If the child is hesitant to enter or stay in the closed chamber, one of the parents or a technician can join the child. During the test, the child has to wear a nose clip, and the cheeks should be firmly supported to avoid upper airway shunting (see above). A mouthpiece or facemask with a modified mouth tube is connected to a pneumotachograph, and the tidal flow is monitored until a stable breathing pattern is established. The principle of the plethysmographic estimation of $sR_{aw}$ is the indirect measurement of the alveolar pressure through the changes in the box pressure or volume ($\Delta V_{box}$) during tidal breathing. $sR_{aw}$ is calculated from the changes in the flow at the airway opening ($\Delta V'$) and $\Delta V_{box}$ as

$$sR_{aw} = (\Delta V_{box}/\Delta V') \times (P_{amb} - P_{H_2O}),$$

where $P_{amb}$ is ambient pressure and $P_{H_2O}$ is the pressure of the water vapor at body temperature; hence $P_{amb} - P_{H_2O}$ is the approximate pressure of the compressible thoracic gas. In the earlier plethysmograph models, the BTPS conditions were achieved by the rebreathing technique, while in the new, commercial devices the correction is accomplished electronically. This is one of the reasons why reference data collected with home-built and commercially available devices are not comparable.[104] Since the first publications, the $sR_{aw}$ test has undergone many modifications, standardization for measurement in young children and reference data from a multicenter study published for children between 2 and 11 years of age (see *Suggested Reading*).

## Quality Control, Acceptability Criteria, and Limitations

The feasibility of the test has improved significantly with the introduction of specifically designed facemasks and with the possibility of an adult accompanying the child in the box. These improvements have made the measurements of $sR_{aw}$ successful in more than half of 2-year-olds and in more than two-thirds of the children at 3 years of age.[105] The success rate of the measurement of $R_{aw}$ in older children is similar to that of spirometry in the same population. It seems however that the test is still not standardized appropriately in children.[105a] If an adult is present in the box during the test, they should be instructed to take a deep breath and have a constant, slow (~20 seconds) expiration while the child's lung function is being recorded.[104] The constant drift caused by the long expiration can be compensated automatically in most of the commercial devices. Importantly, the volume displacement caused by the adult person must be corrected by using an approximate volume based on the body weight. In devices with electronic BTPS correction, it is ideal if the child is breathing at a frequency between 30 and 45; however, this is not always easy to achieve. This is one of the limitations that was introduced during the procedure of simplification and automatization of the technique. Furthermore, it has been shown that the electronic BTPS correction might result in a systematic overestimation of $sR_{aw}$.[104] This also explains why data collected with custom-built equipment using a heated rebreathing system are not comparable with the reference data obtained with commercial devices. The frequency of panting also varies between centers, which further limits the generalizability of $sR_{aw}$.[105a]

The simultaneous recording of the changes in the tidal V′ against the changes in $V_{box}$ (the so-called specific resistive loops, Fig. 11.24) and their observation provide the examiner with important information on the quality and reliability of the test. Obvious artefacts such as coughing, swallowing, and breath holds can easily be recognized real time. A test is acceptable if five artifact-free loops have been recorded. The outcome variable presented depends on the reading of these loops (see the different readings on Fig. 11.24); however, the most commonly reported variable is $sR_{awtot}$, which reflects the relationship between V′ and the maximum change in $V_{box}$. Note here that since the breathing pattern is highly variable in young children, this is reflected in the variable V′ vs. $V_{box}$ loops obtained during tidal breathing. This is responsible for the relatively high within-subject variability of $sR_{aw}$ values, especially when $sR_{awtot}$ is reported (see Fig. 11.24).

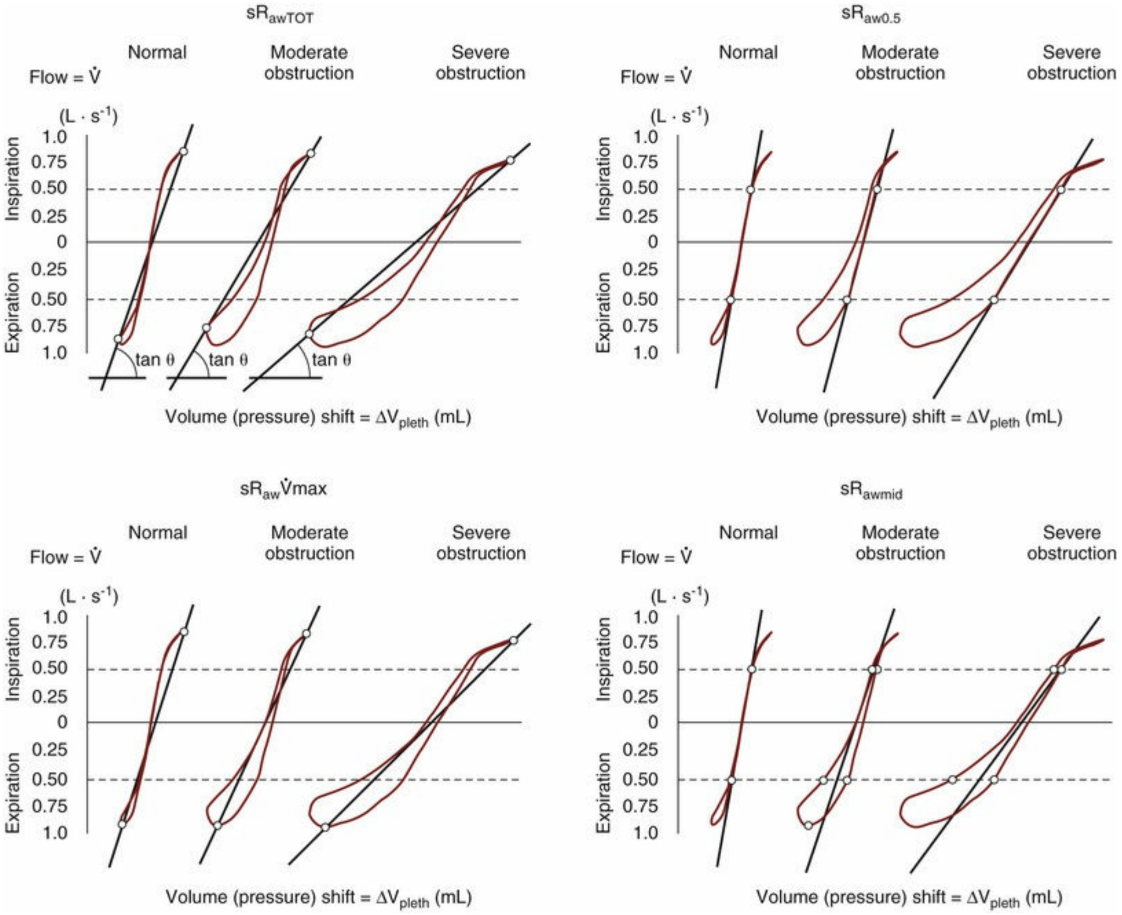

**FIG. 11.24** Specific resistive flow-volume loops obtained with the plethysmographic method in children. An illustration of how different estimates of $sR_{aw}$ may be calculated from the specific resistance loop, depending on how various parameter lines are applied on the loop and the slope of such lines. (Bisgaard H, Nielsen KG. Plethysmographic measurements of specific airway resistance in young children. *Chest.* 2005;128(1):355–362.)

Since $sR_{aw}$ is a product of FRC and $R_{aw}$ without knowing their values separately, it mainly reflects the relationship between lung volume and resistance. Nevertheless, $sR_{aw}$ has been employed in research studies in young children with asthma or CF.[102,106] $sR_{aw}$ was increased in children with parental atopy[107] and was able to discriminate between persistent and late-onset wheeze phenotypes.[108] $sR_{aw}$ has also been useful to assess the response to both bronchodilator[103,109] and constrictor[110,111] agents in asthmatic children. Based on these reports, 25%[103]–42%[109] decrease (bronchodilation) or increase (challenge test) should be considered as clinically significant changes; however, both the clinical and physiological interpretation of these findings requires caution.

## Forced Oscillation Technique

### Summary

- Measurement of respiratory resistance ($R_{rs}$) and reactance ($X_{rs}$) during tidal breathing
- Commercial devices and reference values in children are available
- $R_{rs}$ reflects the resistance of the airways and the tissues, while $X_{rs}$ is determined by the elasticity of tissues and the inertance of the central airway gas
- The conventional estimates of $R_{rs}$ and $X_{rs}$ have limited diagnostic value in individuals
- Within-breath tracking of $R_{rs}$ and $X_{rs}$ at a single frequency reveals different airway dynamics in health and disease

Similarly to the MBW technique, FOT has its renaissance with an in-depth development in the recent years. This includes the introduction of novel methods in both preschool-aged children and infants, and new aspects of interpretation of the data. Therefore in this chapter both MBW and FOT receive a special focus to summarize the current knowledge on these techniques.

The basic principle of the FOT is the application of an external pressure (or flow) signal superimposed on spontaneous breathing (Fig. 11.25), and the measurement of the flow (or pressure) response of the respiratory system.[27,74,112] The oscillatory signals are specifically designed to measure the resistive and elastic characteristics of the respiratory system without relying on or interfering with spontaneous breathing. Since no special breathing maneuvers are involved, the requirement for patient cooperation is minimal; this makes the FOT particularly attractive in young children.[27]

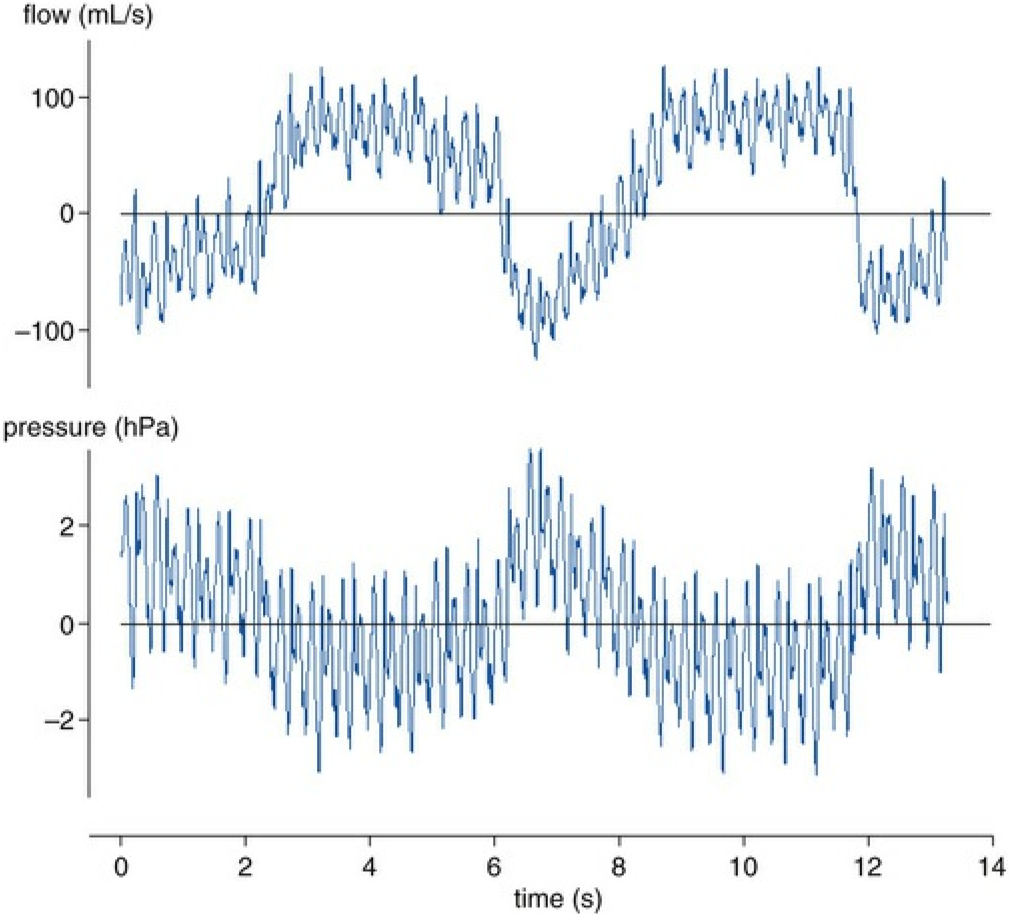

**FIG. 11.25** Superposition of the forced oscillatory and spontaneous breathing signals in a child.

Preschool-aged and older children (similarly to adults) breathe tidally through a mouthpiece in the sitting position, wearing a nose clip and with their cheeks supported (see Fig. 11.20). Single-frequency sinusoids or multiple-frequency composite signals of small amplitude (<2 hPa) are generated by a loudspeaker or a linear motor and transmitted to the airway opening via the measurement head and a bacterial filter. A breathing tube provides a pathway for normal breathing. The input impedance of the respiratory system ($Z_{rs}$) is determined from the relationship between the airway-opening pressure ($P_{ao}$) and the resulting flow ($V'$) at all oscillation frequencies. An alternative device measuring $Z_{rs}$ is the wave tube[113] whose inlet ($P_1$) and outlet ($P_2$) pressures are used in the computation of $Z_{rs}$ (Fig. 11.26).

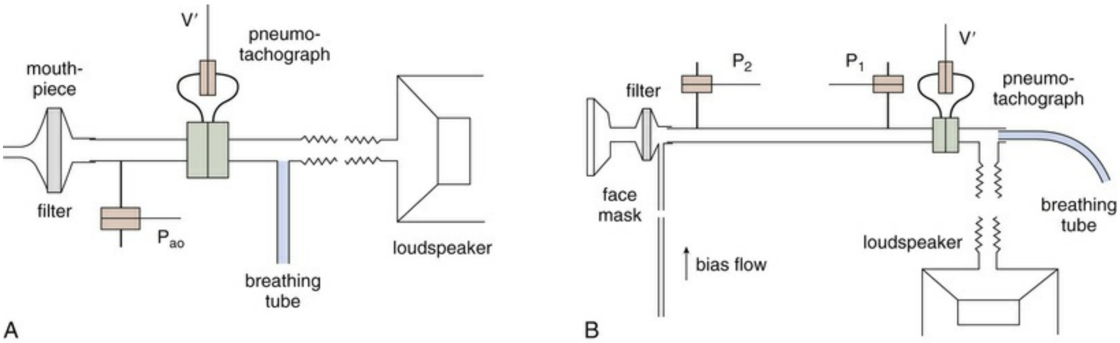

**FIG. 11.26** Schematics of forced oscillatory setups. (A) A conventional arrangement for the estimation of respiratory impedance based on the signals of flow (V′) and airway-opening pressure ($P_{ao}$). (B) A wave-tube setup for measurement of the high impedances in infants, which are computed on the basis of the inlet ($P_1$) and outlet ($P_2$) pressures, as well as the geometrical and material properties of a cylindrical tube. Loudspeakers deliver the computer-generated oscillatory signals; breathing tubes impose low resistance against spontaneous breathing.

While FOT is one of the most popular tests in clinical lung function laboratories in preschool-aged children, its adaptation to infants has been limited to research settings; therefore only the principles of the infant FOT test are summarized here. Similarly to the other infant lung function tests, $Z_{rs}$ is measured in the supine position through a facemask in spontaneously breathing infants during natural sleep (see Fig. 11.1), during which time several $Z_{rs}$ measurements of 30–60 seconds recording time can be collected. Once the baby is asleep, the test should not take longer than 15 minutes. The success rate of the infant FOT test is reported to be between 60% and 90%,[114,115] and mainly determined by the time available for waiting until the infant falls asleep.

## Main Outcome Measures and Their Interpretation

In children, the FOT measurements can be accomplished in a relatively short time (10–20 seconds per recordings), and they provide a multitude of respiratory mechanical data; this is why their interpretation warrants much consideration.

Conventionally, $Z_{rs}$ is expressed in terms of respiratory system resistance ($R_{rs}$) and reactance ($X_{rs}$) as functions of frequency (see Fig. 11.17). As discussed in the *Physiological Principles of the Respiratory Mechanics* section of this chapter, the forced oscillatory signal as the driving pressure equals the sum of the resistive, elastic, and inertial pressures of the total respiratory system. Therefore $R_{rs}$ represents the mechanical properties associated with energy dissipation (airway resistance, $R_{aw}$ and tissue resistance, $R_{ti}$), while $X_{rs}$ is a sum of two opposing energy-storing components: the elastance of the pulmonary and chest wall tissues ($E_{rs}$; the reciprocal of total respiratory compliance, $C_{rs}$) and the inertance ($I_{rs}$) determined primarily by the accelerated gas column in the large airways. Both $R_{rs}$ and $X_{rs}$ exhibit characteristic frequency dependence in both healthy children and adults. As shown in a schematic diagram in Fig. 11.17, at low frequencies $X_{rs}$ follows the course of the tissue reactance, $X_{ti}$, which changes roughly inversely with frequency, and approaches the linear increase of the inertial reactance ($X_{in}$) dominating at higher frequencies. The point where the two reactances are equal in magnitude (i.e., $|X_{ti}| = |X_{in}|$) but opposite in sign is called resonant frequency ($f_{res}$).

$R_{rs}$ is relatively constant in the range 10–20 Hz in infants and children and exhibits an elevation toward both low and high frequencies. Of more physiological significance is the low-frequency behavior of $R_{rs}$, where the marked frequency-dependent change is caused by the contribution of $R_{ti}$ which in turn mirrors the change of $X_{ti}$ (see Fig. 11.17). At normal breathing rates, the contributions of $R_{aw}$ and $R_{ti}$ to $R_{rs}$ are comparable, while $X_{rs}$ is basically determined by $X_{ti}$; however, this low-frequency region can be explored only in the absence of breathing activity by the LFOT.[75,116] During spontaneous breathing in young children and infants, the relatively high breathing frequency interferes with the oscillation signal; therefore reliable values of $R_{rs}$ and $X_{rs}$ cannot be obtained at frequencies lower than 4, 6 (older children, preschoolers) or 8 Hz (infants).

Conventionally, $Z_{rs}$ is obtained from a number of averaged recordings, each covering several breaths; thus $R_{rs}$ and $X_{rs}$ represent mean values from the whole breathing cycle. The most commonly reported variables of a FOT measurement are the average values at low frequencies (i.e., $R_{rs}$ or $X_{rs}$ at 6 or 8 Hz). $f_{res}$ and the area between $X_{rs}$ curve and x-axis (AX) are important outcome measures that provide information on the global characteristic of the $X_{rs}$ curve. Unfortunately, as a result of the low lung compliance in the early years, $f_{res}$ is not always reached in the measured frequency range in preschool-age children (Fig. 11.27). In the presence of respiratory disease, this delayed course of $X_{rs}$ below the AX can be more significant (see below). AX is theoretically calculated between the lowest measured frequency and $f_{res}$; however, some devices still display AX values when $f_{res}$ is not achieved in the measured frequency range. Therefore the AX values reported in young children should always be treated with caution. An increased AX and $f_{res}$, however, are useful outcome measures in older children, reflecting inhomogeneous constriction of the peripheral airways.[74]

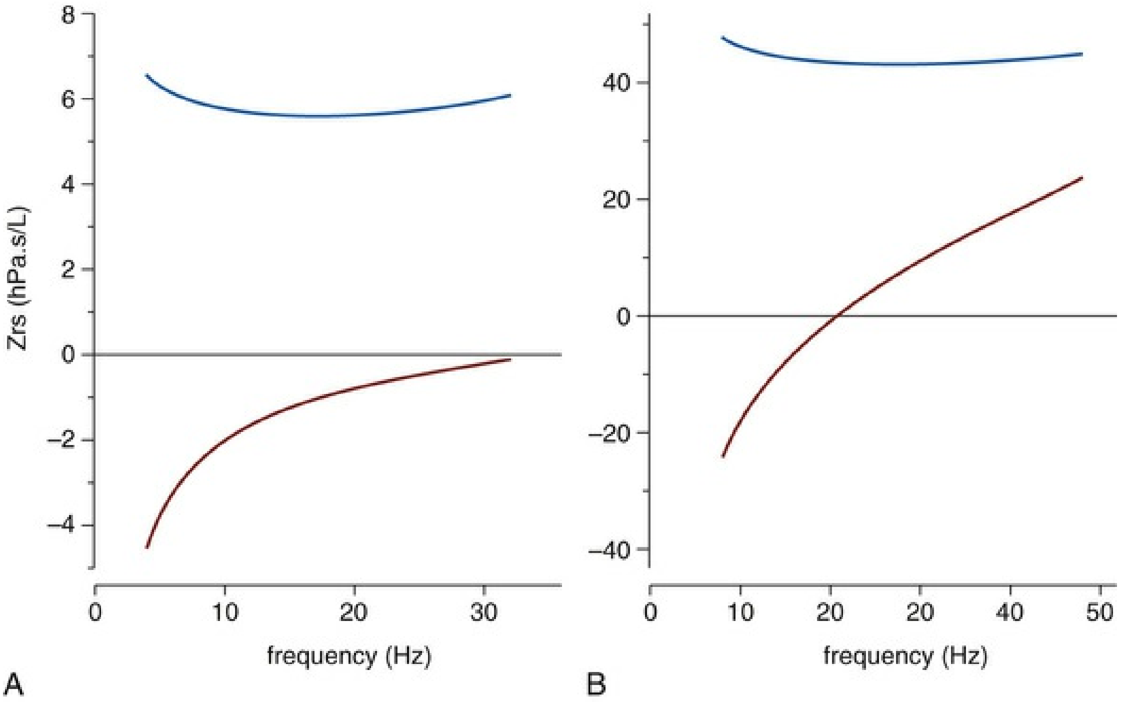

**FIG. 11.27** Schematic illustration of impedance (Zrs)

curves in terms of resistance *(blue lines)* and reactance *(red lines)*, measured in a healthy 4-year-old child (A) and a healthy newborn infant (B), using different scales in Zrs. Note the lack of resonant frequency in the measured frequency range (4–32 Hz) in the 4-year-old child and the steep rise in reactance, due to the inclusion of the nasal pathways, in the infant.

In the frequency range that can be covered with FOT during normal breathing there is an interval where $R_{rs}$ is relatively independent of frequency, and which covers the transition of $X_{rs}$ from the dominance of elastance to that of the inertance. In this range, $Z_{rs}$ can be described by a simple resistance (R)–inertance (I)–compliance (C) model.[117,118] However, departure from this ideal frequency, dependence of $Z_{rs}$ may occur for several reasons that introduce a negative frequency dependence of $R_{rs}$ and/or a retarded negative course in $X_{rs}$: (1) involvement of $R_{ti}$ at lower frequencies; (2) insufficient support of the cheeks, that is, the upper airway artifact[119]; (3) other airway wall shunts proximal to an elevated bronchial resistance[120]; and (4) peripheral inhomogeneities, that is, lung units with different time constants.[121] $R_{rs}$ at the upper frequency part (>20 Hz) can be a measure of the resistance of the large proximal airways, whereas the higher values of resistance at less than 10 Hz reflect the involvement of the mechanisms (1)–(4) listed above. It is therefore a simplistic and wrong approach when the low-frequency $R_{rs}$ is regarded as the simple sum of the central and peripheral resistances.

While most of the lung function outcome measures are easy to understand and put in a physiological context, the concept and the interpretation of the reactance remains one of the most difficult tasks in respiratory mechanics. As discussed previously, $X_{rs}$ is far more complex than a variable that reflects the tissue elasticity. Nevertheless, the future direction of the conventional application of the FOT might include the (re-)introduction of the R-I-C model fitting in infants and preschool-age children.[121a] Compliance obtained from this model fitting might be a term easily embraced by researchers and clinicians. Since neither $f_{res}$ nor AX can be obtained reliably in preschool-age children, compliance can be a robust descriptor of the whole reactance curve (as it is obtained from all the measured reactance values) instead of reporting $X_{rs}$ at a single frequency. However, once the R-I-C model becomes obviously inconsistent with the measured $Z_{rs}$ data (as in severe impairments in respiratory mechanics), the derived parameters lose physiological relevance. It is also important to note here that while the concept of compliance is easy to deal with, the values of C derived from $Z_{rs}$ remain affected by the same factors that influence reactance; therefore a low compliance value will not always reflect decreased lung elasticity. Finally, as mentioned earlier in this chapter, the values of C determined by the FOT are not comparable numerically with that of the $C_{rs}$ obtained at breathing frequencies (e.g., with SOT) or during static conditions (i.e., weighted spirometer technique).

Since infants are preferential nasal breathers, the measured $Z_{rs}$ includes the impedance of the narrow upper airways, which makes the inference to the resistance of the lower respiratory system difficult. This is one of the main reasons why $C_{rs}$ measured with the FOT has been reported as a potentially useful outcome measure over $R_{rs}$.[114] The effect of the nasal pathway is also obvious on the $X_{rs}$ curve as the inertance of the respiratory system is much more significant in nasal breathers than when $Z_{rs}$ is measured through the mouth. This explains the relatively low $f_{res}$ in infants (see Fig. 11.27) despite their low lung compliance.

The main limitation of the FOT in preschool-age children is the wide range of healthy reference data for a given height (see Fig. 11.21), which explains why the current FOT studies have shown limited clinical potential in individuals. To overcome this problem, novel aspects of the methodology have been suggested and new outcome variables have also been introduced.[122] The biggest dataset in preschool-aged Caucasian children has recently been published and z-scores (including those for R and C) were created for this very unique population.[121a]

Intensive investigation has focused on the measurement and interpretation of the dynamic changes of respiratory mechanics during the breathing cycle.[122–125] The most important point of the new concept is that instead of considering the average values of $R_{rs}$ and $X_{rs}$ over several breaths and their frequency dependence, a fast single-frequency signal is employed to track the within-breath fluctuations of $R_{rs}$ and $X_{rs}$. The analysis of $R_{rs}$ and $X_{rs}$ in different phases of the breathing cycle and their changes with tidal flow and volume can provide us with unique information on respiratory mechanics.

## Quality Control, Acceptability Criteria, and Limitations

The calibration of the FOT device is exceptionally critical, and the proper concept of the calibration is not always embraced by the manufacturers. The calibration requires a device with known impedance that should be appropriate for the largest $Z_{rs}$ values expected in the measured population. Since $Z_{rs}$ is much higher in children than in healthy adults, a calibration device with a minimum impedance of 15 hPa.s/L should be used (we note here that the impedance of an adult with chronic obstructive pulmonary disease [COPD] can sometimes reach a $Z_{rs}$ as high as 30 hPa.s/L; therefore a low-impedance calibration device is not recommended for adults either). In infants, $Z_{rs}$ is 4–5 times higher than in preschool-age children, and the calibration of the infant setup requires a calibration device with a $Z_{rs}$ of at least 80 hPa.s/L. Currently, only the wave-tube FOT setting[115] proves accurate enough to measure $Z_{rs}$ in these extreme ranges.

As a part of the calibration, the impedance of the bacterial filter and the mouthpiece should be extracted from the measured $Z_{rs}$. In addition to the resistance of the filter, the shunting effect of the mouthpiece gas compliance can also be significant in young children with lung disease; therefore its correction requires a comprehensive approach. The method of mouthpiece correction differs between manufacturers, and it is not known for the users; this might contribute to the fact that reference values collected with different devices are not always comparable.

In children, at least three technically acceptable recordings of $Z_{rs}$ must be obtained. The recording time varies between commercial devices but usually takes at least 15 seconds and should cover at least 3–5 tidal breathing cycles. A recording can be considered artifact-free if there is no leak around the mouthpiece, and no vocalization, cough, or swallowing occurs during the test. Temporary increases in $P_{ao}$ and decreases in V′ indicate epochs of upper airway closure. The artifact that is the most difficult to recognize is the small leak around the mouthpiece; this may be detected via increases in $R_{rs}$ and $X_{rs}$ at the lowest frequencies (Fig. 11.28). Recently, automatized artefact-detection system has been proposed[125a]: its usefulness in the everyday practice, particularly in children requires further research. Although the breathing pattern has a high natural variability in children, it is ideal if both the breathing frequency and tidal volume values are in the normal range for the child's age.

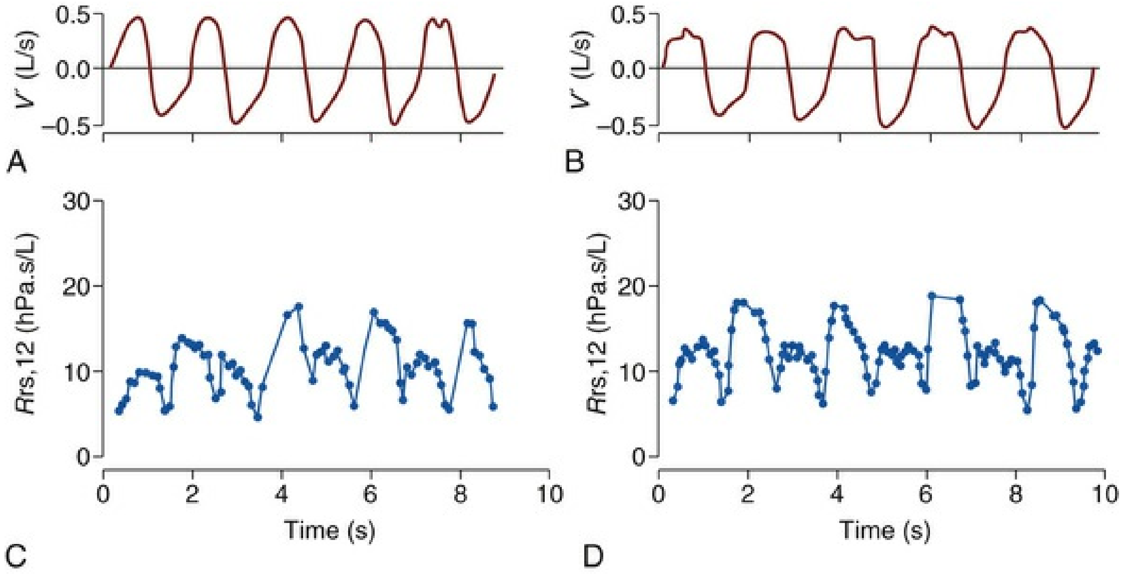

**FIG. 11.28** Representative time courses of: (A and B) tidal flow (V′) and (C and D) respiratory resistance ($R_{rs}$) at 12 ($R_{rs}$,12) and 20 Hz ($R_{rs}$,20) at baseline. Flow values are negative during expiration. Both $R_{rs}$,12 and $R_{rs}$,20 show periodic within-breath fluctuations. Most of the $R_{rs}$ variation is reflected in the absolute value of the tidal flow. (Marchal F, Loos N, Monin P, et al. Methacholine-induced volume dependence of respiratory resistance in preschool children. *Eur Respir J*. 1999;14(5):1167-1174.)

The assessment of the reliability of the $Z_{rs}$ data is important.

Although the commercial devices report coherence values and set acceptance limits for $Z_{rs}$ based on them, the coherence values are dependent on their calculation that varies between manufacturers and is usually not transparent to the users. Importantly, coherence has been shown unreliable in the presence of nonlinearities (an inherent property of the respiratory system during breathing) and multifrequency oscillations typically used in the FOT devices.[126] Therefore the interpretation of these values in young children requires caution and cannot be considered as the main acceptability criteria of a test. Inspection of large measurement sets indicates that a high coherence value in young children does not always belong to an acceptable test, while low coherence does not always reflect poor quality. In young children, the reproducibility of the $Z_{rs}$ spectra is far more important, and the measurement can be considered acceptable if: (1) it is artifact free, (2) the values and the shape of the impedance curves are appropriate for the age (and disease status) of the child, and (3) the $Z_{rs}$ spectra are reproducible if the $R_{rs}$ and $X_{rs}$ values are within a 10% range of the $Z_{rs}$ magnitude at the lowest frequencies measured. As in spirometry, experienced technicians or clinicians can also obtain useful information from the observation of the $Z_{rs}$ versus frequency diagrams (frequency dependence of $R_{rs}$ and $X_{rs}$, repeatability, etc.).

## Potential Clinical Applications in Children

Findings on the clinical utility of the FOT in respiratory disease are controversial. In children with CF, FOT is able to detect the early lung disease[127]; however, it has been shown recently that the alterations in the outcome measures of FOT seem to be independent of the clinical symptoms, presence of inflammation, and structural abnormalities.[128] Furthermore, in older children $R_{rs}$ has failed to discriminate between healthy children and those with CF[102,129,130] even when $FEV_1$ was decreased.[102,130] These findings suggest that the mean value of $R_{rs}$ is unlikely to be sensitive for peripheral airway obstruction. In infants with CF, resistance has shown a relationship with pulmonary inflammation[131] when measured with the LFOT.

Follow-up studies on infants with neonatal chronic lung disease have reported increased $R_{rs}$ and more negative $X_{rs}$ during the preschool-[132] and school-age years.[133,134]

Similarly to CF, the diagnostic power of the conventional estimates of $R_{rs}$ and $X_{rs}$ in young individuals with recurrent wheeze and asthma appears to be highly limited. $R_{rs}$ and $X_{rs}$ were able to discriminate between children with different types of wheeze and healthy children (although rather statistical than clinical significance was reported),[135] while other studies with smaller sample size have not found such difference.[136,137] $Z_{rs}$ measures have also been investigated in response to both bronchodilator[136,138–141] and bronchoconstrictor[142,143] agents, and the clinically significant (relative) changes in $R_{rs}$ at 6, 8, and 10 Hz have been established between 32% and 40%.

It has been reported in various research and clinical settings that FOT is a highly feasible lung function test in young children as young as 2 years of age. Despite the great feasibility, FOT has been suggested to have limited clinical potential in the clinical management of individuals with lung disease. This is most probably due to the combination of a number of factors that affect $R_{rs}$ during tidal breathing in both healthy children and those with lung disease.[122,144]

Studies employing a single-frequency signal have revealed that $R_{rs}$ shows a characteristic fluctuation throughout the breathing cycle (Fig. 11.29): it has its minimum at the transitions between inspiration and expiration, while it is increasing with both inspiratory and expiratory flows, reaching its maximum value at the peak expiratory flow.[122,123,145] With this faster signal (usually 10 or 12 Hz in young children), the inspiratory and expiratory $R_{rs}$ (and $X_{rs}$) values are easy to separate. Inspiratory resistance was found to correlate better with $R_{aw}$ (measured with plethysmography) than expiratory resistance,[145] and this is likely to be explained by the narrowing of the glottic aperture during expiration. The clinical value of the separate assessment of inspiratory and expiratory $X_{rs}$ values remains unclear in children (while it is extremely useful in adults with COPD). The option of the use of a single-frequency signal and the separation of inspiration and expiration is now available in some of the commercial devices.

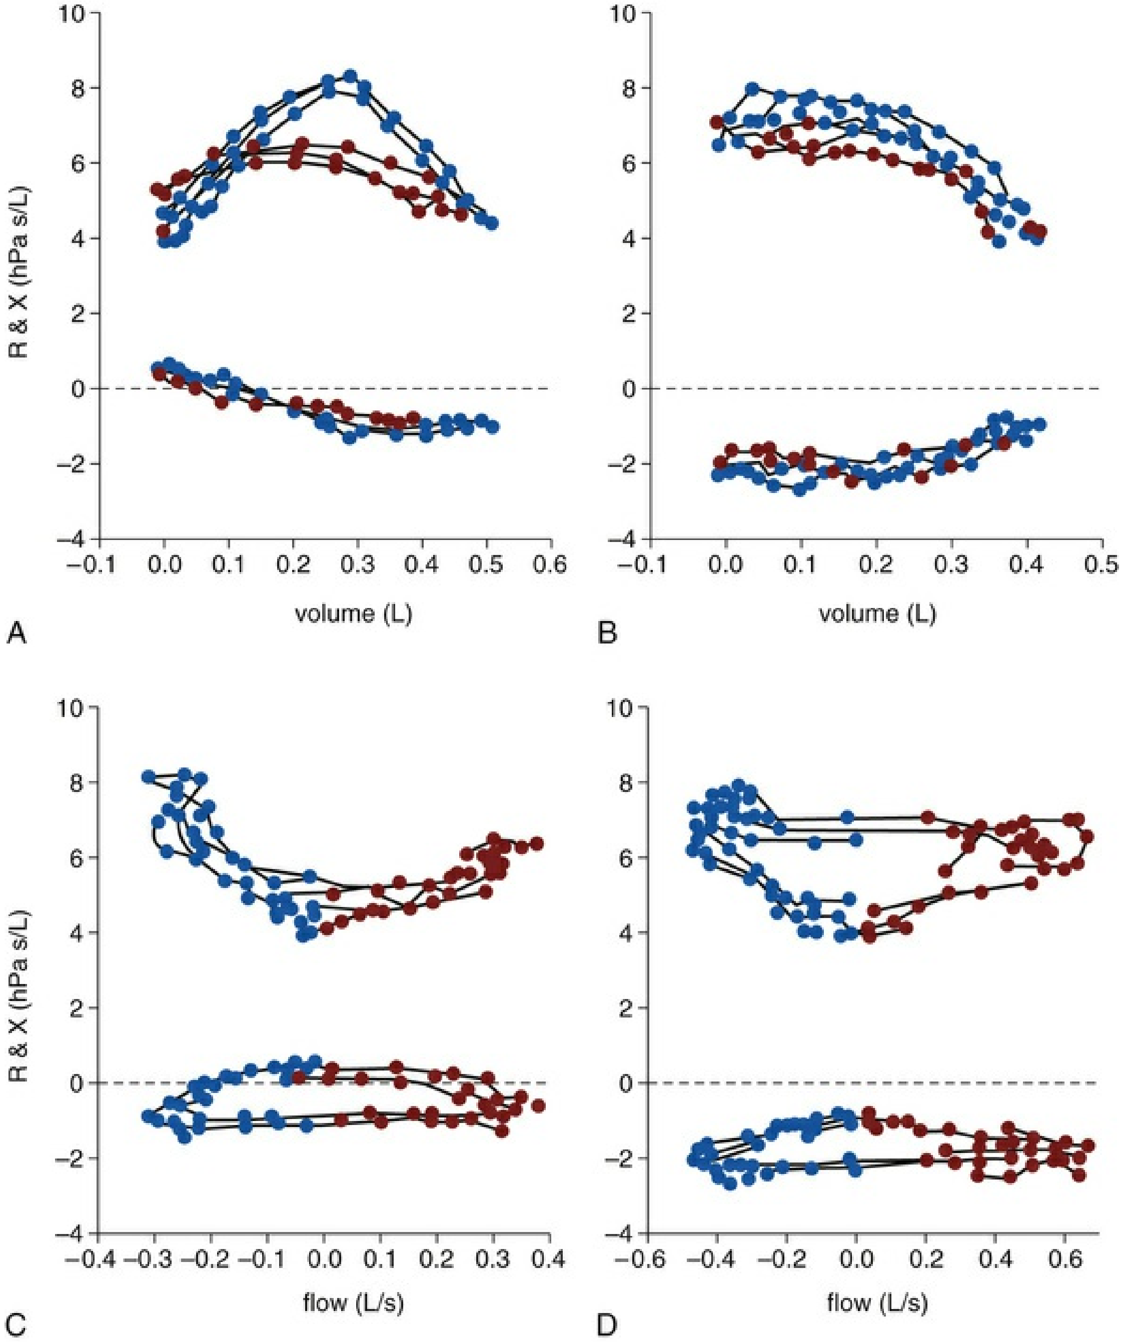

**FIG. 11.29** Tidal changes with volume (A and B) and flow (D and C) in resistance (R, *top*) and reactance (X, *bottom*) during inspiration *(open circles)* and expiration *(closed circles)* in a healthy subject (A and C) and in a child with acute airway obstruction (B and D). Note the elevated end-expiratory resistance (B, "0" volume) and the increased hysteresis (D) in the presence of airway

obstruction. (Czovek D, Shackleton C, Hantos Z, et al. Tidal changes in respiratory resistance are sensitive indicators of airway obstruction in children. *Thorax*. 2016;71(10):907-915.)

A recent study has also suggested that if the within-breath changes of $R_{rs}$ are tracked over many breathing cycles, phases can be identified where the values of $R_{rs}$ are the least affected by the variable breathing pattern of young children. Reading $R_{rs}$ at the end-expiration and at end-inspiration (i.e., where tidal flow is zero and $R_{rs}$ is at its minimum) may provide a better estimate of the airway caliber and reveal the volume-related changes in $R_{rs}$ (see Fig. 11.28). Indeed, the difference between end-expiratory and end-inspiratory $R_{rs}$ values has been shown to be a sensitive and specific indicator of airway obstruction in children with both acute and recurrent wheeze.[122]

Although these novel approaches of the FOT have a great clinical promise, their validation requires multicenter collaboration that can carefully assess the clinical utility of the within-breath FOT in different patient groups and different settings. Nevertheless, robust reference values for the new intra-breath Zrs measures are in press, which will improve the clinical utility of this technique in the detection of lung disease in young children.

## Measurement of Gas Mixing

Detection of ventilation inhomogeneity with a noninvasive lung function test has been of primary interest to researchers and respiratory physicians for many decades. Two methods have been developed for this purpose: the single breath washout (SBW) and MBW techniques. Similarly to spirometry, SBW requires high cooperation from the subject to perform a well-coordinated, complete TLC maneuver for the assessment of the gas-mixing capacity of the lungs over a wide range of lung volumes. Since the use of SBW is not feasible in infants and young children, we will restrict to discussing the MBW technique in this chapter.

### Multiple Breath Washout Technique

## Summary

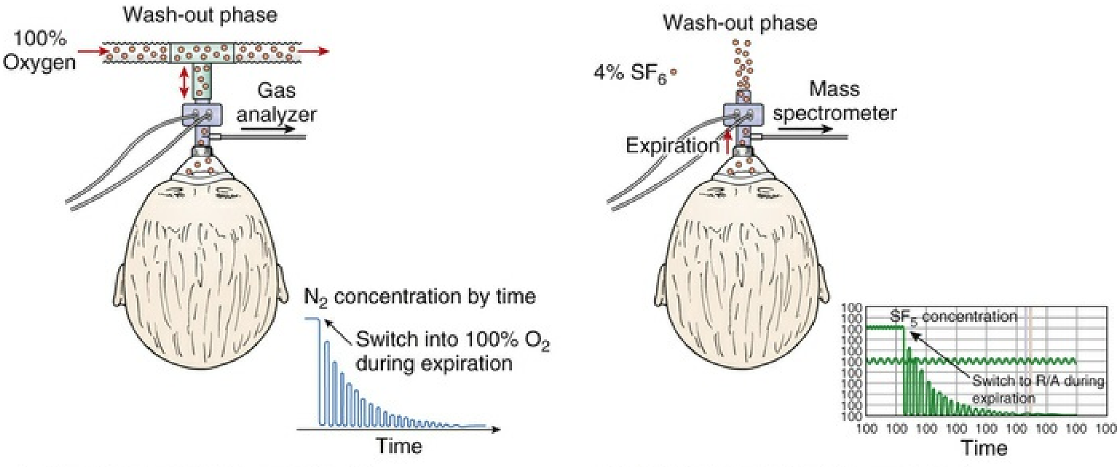
- ▪ Measurement of FRC and LCI in tidally breathing subjects
- ▪ Commercial devices are available for both infants and children
- ▪ Data collected with different devices, gases, and analytic methods are not comparable
- ▪ Main limitations are the inconsistent methodology and the time required for the test
- ▪ Clinical potential in CF

MBW has been a focus for clinical research studies in both infants and young children in recent years, as its application requires only tidal breathing and it provides unique information on the overall ventilation inhomogeneity in the lungs. Although the physiological background and importance of the measurement of "uneven ventilation" via the gas-mixing ability of the respiratory system were already described in the 1940s[146] (see also the *Measurement of Lung Volumes* part of this chapter), its precise assessment has required technical development and a high level of computerization. Nowadays, different commercial devices specifically designed for infants and preschool-aged children are available; however, the method of measurement, the software algorithms, and the outcome measures vary between these devices. To aid the general application of MBW in patients with lung disease, an ERS/ATS consensus statement was published in 2013 (see *Suggested Reading*). There has also been a great effort to modify and standardize the technique for the special needs of infant and preschool-aged children. Despite the intensive research on the clinical utility of the MBW in children (with more than 80 peer-reviewed articles published on this topic only between 2013 and 2017) and its promising clinical potential, it is still far more frequently used in research settings than the everyday clinical practice.

## Physiological Principles and Assumptions

The main principle of MBW is the continuous measurement of the changes in the exhaled concentration of an inert gas simultaneously with the tidal flow over many breathing cycles in spontaneously breathing subjects. Various gas mixtures can be used for the MBW test; however, the measured gas has to fulfill the following criteria: it has to be safe to inhale and should not transfer through the alveolar wall into and from the circulation and tissues. In other words, the aim is to measure the alveolar ventilation independently of the influence of circulation and diffusion. The cheapest and the most widely used method is the $N_2$ washout technique, since $N_2$ can be considered as an intrinsic inert gas in the respiratory system. However, it is well documented that $N_2$ is also excreted into the lungs from the tissues, which can be responsible for as much as 1% of the total $N_2$ concentration in the respiratory system. Although different correction methods for the tissue $N_2$ have been suggested,[146a] complete solution of this problem requires further research. Additionally, pure oxygen (which is used to wash the $N_2$ out of the respiratory system) affects the breathing pattern in infants; therefore the $N_2$ washout technique cannot be used in this age group. The most commonly used test gas in infants is sulfur hexafluoride ($SF_6$, delivered into a closed circuit via bias flow in a concentration of either 4% or 5%) with 21% $O_2$ balanced with $N_2$. $SF_6$ has many advantages over $N_2$ being an extrinsic inert gas (i.e., not present in the human body), the detection of the changes in the alveolar concentration of $SF_6$ is technically easier and provides more reliable and precise results. However, $SF_6$ is expensive, not registered for human use in many countries, and was also recognized as an "extremely potent greenhouse gas."

Since $N_2$ is already present in the respiratory system (intrinsic inert gas), no wash-in phase is required for the $N_2$ MBW technique, which makes the protocol shorter compared to other gases (e.g., He, $SF_6$). At the beginning of the test, the alveolar concentration of $N_2$ can be considered to be 80%. Before the washout phase begins, the patient is breathing room air from an open circuit (Fig. 11.30) while the concentration of $N_2$ and the tidal flow are being recorded. Once the breathing pattern is stable and at least 5 steady-state breathing cycles are recorded as baseline, the circuit is switched to pure oxygen (closed circuit) at the end of the last breathing cycle of the wash-in phase. This step is crucial for the correct calculation of FRC (for details of the calculation of FRC from gas mixing, see the part *Measurement of Lung Volumes* of this chapter). This can be particularly challenging in children because of their high breathing frequency (especially when unwell), and therefore the test requires an experienced examiner. The basic assumption of MBW is that the known end-expiratory concentration of the test gas (in this case $N_2$) will be diluted with every breath that the subject takes from the test gas-free gas mixture (in the case pure $O_2$) during the washout phase. The alveolar concentration of the test gas is thus decreasing with each breath during the washout phase, and the test finishes when the concentration of the test gas has decreased below 1/40 of its original alveolar concentration. In healthy lungs with homogenous ventilation, this dilution to 1/40 will happen faster (i.e., fewer breaths are required to clear the test gas from the lungs) than in the presence of lung disease where the parallel lung units have different time constants—this is the simple assumption underlying the potential clinical use of MBW.



Wash-out phase

**FIG. 11.30** Schematic representation of two washout phase tests using the two techniques. (A) $N_2$-based setup. During the $N_2$ washout, 100% oxygen is

delivered using a bias flow. The blue tracing shows the decay in the $N_2$ signal during expiration. (B) Extrinsic gas, $SF_6$-based setup. The green tracing shows the decay in the $SF_6$ concentration during the washout-phase. *R/A,* Room air. (Subbarao P, Milla C, Aurora P, et al. Multiple-breath washout as a lung function test in cystic fibrosis. a cystic fibrosis foundation workshop report. *Ann Am Thorac Soc*. 2015;12(6):932-939.)

In infants, the washout precedes a long wash-in phase, lasting until the concentration of $SF_6$ (which is 0% before the test) is equilibrated in the lungs as indicated by the same inspiratory and expiratory concentrations (4% or 5%) of $SF_6$ (see Fig. 11.30). The washout phase starts when the expiratory concentration of $SF_6$ is stable for at least 5 consecutive breaths. When washout begins, the circuit is opened to room air (open circuit) and the decreasing concentration of $SF_6$ is detected continuously. The test ends when the concentration of $SF_6$ falls below 1/40 of its original concentration for at least 3 consecutive breaths.

## Main Outcome Measures of Multiple Breath Washout

During the MBW test, the concentration of the test gas and the tidal flow are continuously recorded. The inspiratory and expiratory volumes are calculated with the integration of the flow signal. The calculation of FRC, one of the main outcome measures, has been discussed in detail earlier in this chapter (see *Measurement of Lung Volumes*).

Many attempts have been made to properly quantify the washout phase of the test. Historically, $N_2$ dilution was measured in healthy subjects and patients with emphysema when researchers recognized that after a few minutes of breathing pure $O_2$, $N_2$ nearly disappeared from the exhaled gas in healthy subjects while $N_2$ concentration was still high in patients with emphysema.[146] Therefore the time that was required to decrease the $N_2$ concentration to 2% of its original alveolar concentration was used as the main outcome variable.[147] However, it was realized early that the time of the measurement not only depends on the heterogeneity of the ventilation but also on the minute ventilation of the subject (i.e., higher breathing frequency or tidal volume result in faster washout of the test gas, Fig. 11.31). To standardize the test and minimize the effect of the breathing pattern on the reading of the test, the term "turnover" (TO) was introduced. One turnover is the cumulative expiratory volume which is equivalent to the subject's FRC. The number or turnovers that are required to decrease the concentration of the tracer gas to 1/40 of its initial concentration—called the LCI[148]—is the most commonly reported outcome measure to date. LCI is calculated as the cumulative expired volume (CEV) normalized by FRC ($LCI = CEV/FRC$). The value of LCI indicates the overall lung ventilation homogeneity at the point when the test gas is cleared from the lungs. LCI is expected to be increased (i.e., more TOs are needed to clear the gas from the lungs) in respiratory diseases where the ventilation inhomogeneity is increased. According to the guidelines, LCI is read at the end of expiration of the first of three consecutive breathing cycles where the concentration of the tracer gas remains below 1/40.

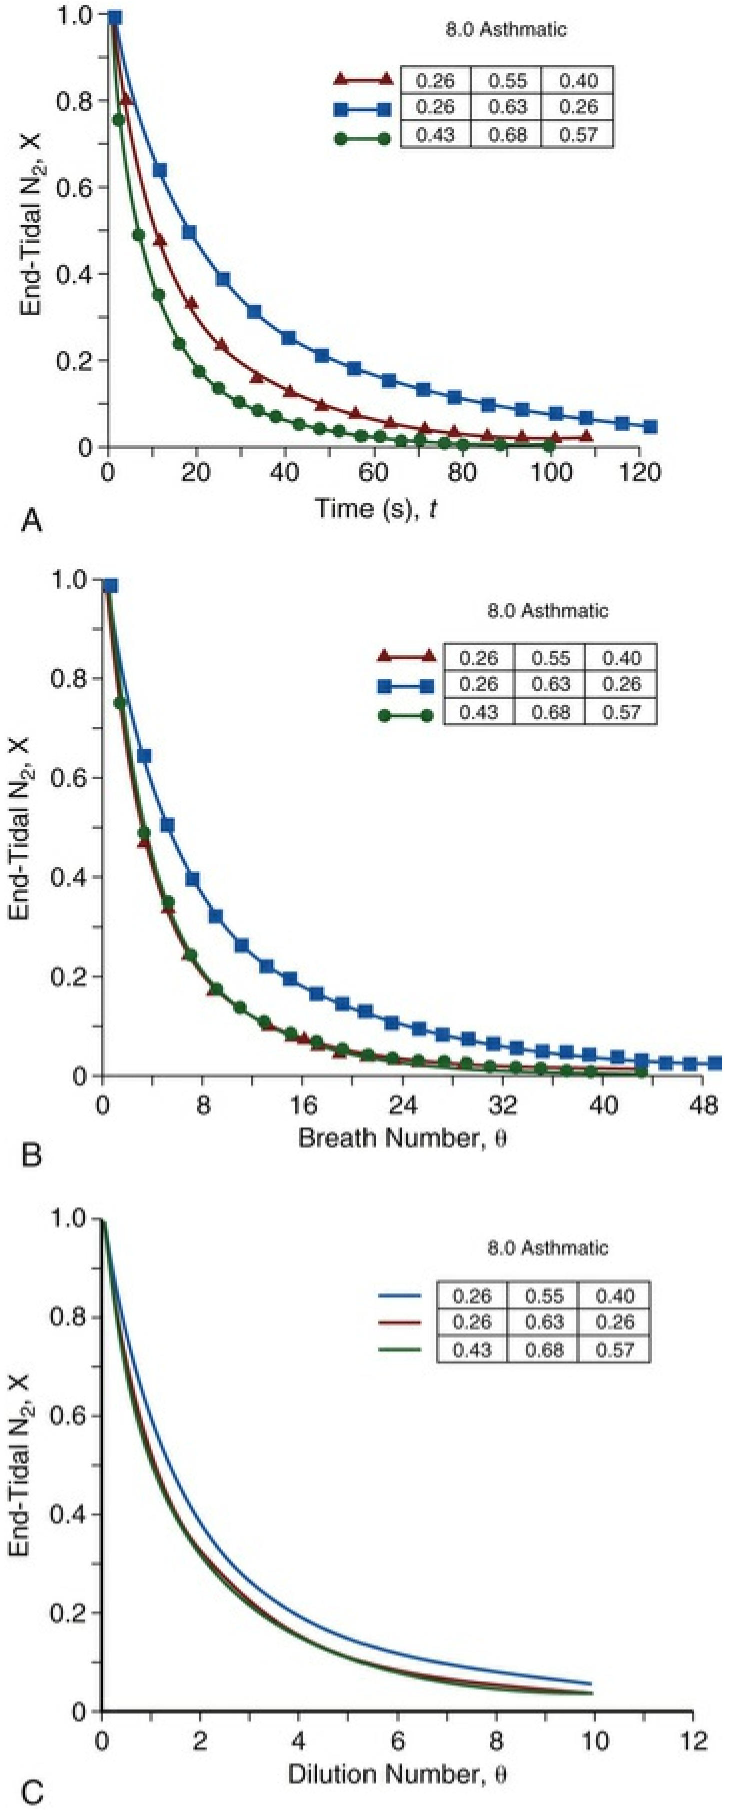

**FIG. 11.31** Reproducibility of the washout curve. Data

from three washout runs performed with a variety of breathing patterns by an asthmatic (BG). Washout curve is graphed with ordinate variable normalized end-tidal nitrogen fraction, X, and abscissa variable: A: time (seconds), t; B: breath number, θ; C: dilution number, η. Dilution number (so called the turnover in the newest terminology) is the least affected by the variable breathing frequency and tidal volume as indicated by the reproducibility of the washout curves within the same subject (C). (Saidel GM, Salmon RB, Chester EH. Moment analysis of multibreath lung washout. *J Appl Physiol*. 1975;38(2):328-334.)

Although LCI is the most commonly used variable in pediatric clinical research studies, it has some limitations that can be important especially in young children with lung disease. LCI is affected by changes in the breathing pattern during the test, and it sometimes takes too long to reach the target concentration. While LCI reflects the general ventilation inhomogeneity, alternative outcome measures have been introduced to facilitate identifying the parts of the lungs that are mainly responsible for the uneven ventilation and describing the underlying mechanisms.

In 1975, Saidel and his colleagues proposed a novel analysis for the washout curve that takes the entire curve into account by analyzing the shape and well-defined parts of the *normalized end-tidal tracer gas concentration (Cnet) vs the number of turnovers* curve.[149] This is the moment analysis, which is less influenced by the changes in the breathing pattern during the test and which makes it potentially useful in pediatric patients (Fig. 11.32). Despite all these advantages of the moment ratios, they are still rarely reported, since their clinical interpretation is difficult, while LCI appears to be more straightforward for researchers and clinicians. The area under the curve represents the zero*th* moment (M0), the first moment (M1) is calculated as *Cnet*TO*, and the second moment (M2) is equal to $Cnet*TO^2$. This calculation of M1 and M2 results in weighted values of area segments of the curve with M1 reflecting the center of the curve while M2 is more influenced by the tail regions (i.e., the TOs at low concentrations). The relationships between these moments have been studied and M1/M0 (first moment ratio) was found to represent mainly the mean, nonuniform alveolar flow distribution while M2/M0 (second moment ratio) accounts more of the lung regions that empty late during the washout. Moment ratios are generally calculated for all the TOs (starting from the first breath of the washout and finishing with the first breath of 3 consecutive breath below a concentration of 1/40).

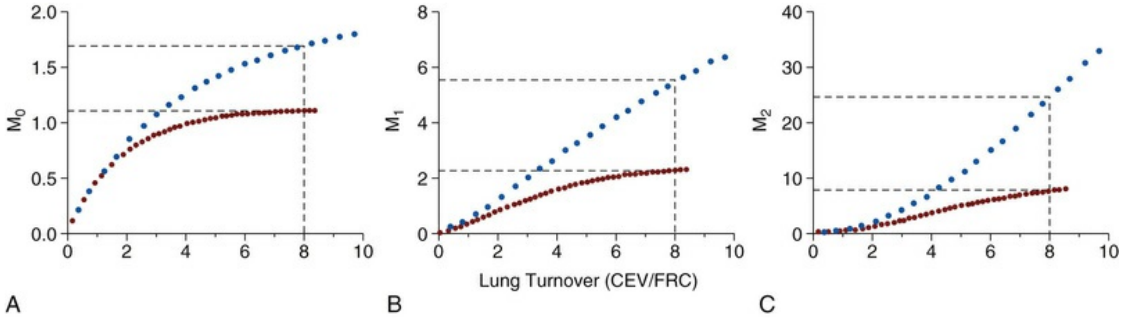

**FIG. 11.32** Illustration of concept of moments. Graph shows moments derived from multiple breath washout ($SF_6$) in term infant *(red circles)* and preterm (gestational age, 28 weeks) infant with chronic lung disease of infancy at 38 weeks postmenstrual age *(blue circles). Dotted lines* indicate values for moments at eight lung turnovers (TO). (A) 0th moment (M0), obtained from area under normalized tracer concentration vs. TO graph. (B) First moment (M1) derived from area under curve described by A. (C) Second moment (M2) derived from area under curve described by B. As moment number increases, there is increased weighting toward end of washout trace. *CEV,* Cumulative expired tidal volume; *FRC,* functional residual capacity. (Pillow JJ, Frerichs I, Stocks J. Lung function tests in neonates and infants with chronic lung disease: global and regional ventilation inhomogeneity. *Pediatr Pulmonol*. 2006;41(2):105-121.)

An alternative way to analyze the shape of the washout curve is the phase III slope ($S_{III}$) analysis (Fig. 11.33), which can be done for each breath during the washout phase. The two main outcome measures of the $S_{III}$ analysis are $S_{cond}$ and $S_{acin}$. In theory, $S_{cond}$ reflects the contribution of the conductive airways while $S_{acin}$ represents the contribution of the acinar airways to the global ventilation inhomogeneity.[150] The analysis of $S_{III}$ was originally developed in studies on adults where tidal volume was maintained at a certain level throughout the test. However, it has apparent limitations in small children: if tidal volume does not exceed a certain limit, $S_{III}$ cannot be identified, and a variable tidal volume also affects the $S_{III}$ analysis, making the interpretation of these variables difficult or misleading.[151] While sometimes $S_{cond}$ and $S_{acin}$ can be calculated in preschool-age children, the high breathing frequency and low tidal volumes make it impossible to identify and hence analyze the $S_{III}$ during infancy. The analysis of $S_{cond}$ and $S_{acin}$ has been proven useful in older children in situations when alveolar compartment and the conducting airways need to be assessed separately.[151a,151b] The clinical significance of outcome measures other than LCI requires further evidence.

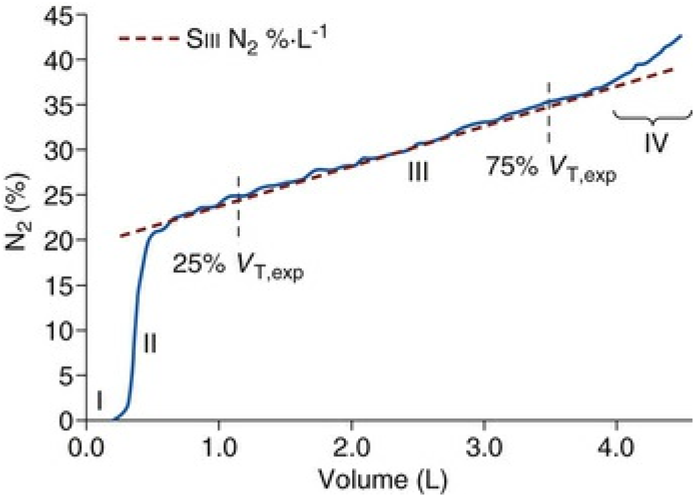

**FIG. 11.33** Example of a typical single-breath washout (SBW) trace and the explanation of the phases of the washout curve within-a-breath. Nitrogen gas ($N_2$) expirogram showing calculation of phase III slope (SIII) in a vital capacity SBW test in a 60-year-old smoker. SIII is calculated between 25% and 75% of the expired volume, to avoid the contribution of phase IV. The four phases of the expirogram are also demonstrated: phase I (absolute dead space), phase II (bronchial phase), phase III (alveolar phase), and phase IV (fast rising phase at end of expiration). Closing volume (CV) is the expired volume (L) from the start of the upward deflection where phase IV starts, to the end of the breath. If residual volume (RV) is known, closing capacity (CC) can be calculated: CC = CV + RV. VT,

exp: expired tidal volume. (Robinson PD, Latzin P, Verbanck S, et al. Consensus statement for inert gas washout measurement using multiple- and single-breath tests. *Eur Respir J*. 2013;41(3):507-522.)

# Feasibility in Older Children

## Quality Control, Acceptability Criteria, and Limitations

The proper installation of the MBW device is crucial for the test. Since the test requires gas cylinders or wall gas, the portability of the device is largely limited and this has to be considered at the time of installation. This factor makes the bedside use of the test difficult or sometimes impossible. Furthermore, commercial devices and $SF_6$ cylinders are expensive; therefore MBW is not widely available at the moment for infant studies.

There are special requirements of the settings in infants and preschool-age children that the examiner has to address before recording the first test. Since the calculations of FRC and LCI are strongly dependent on the dead space, minimization of the dead space is an absolute must for the test in young children.[152,153] Additionally, the volume of the dead space compared to the tidal volume is relatively higher in infants and young children than in older children or adults; therefore settings using a mass spectrometer as a gas analyzer are preferable: the equipment dead space is smaller and it detects the gas concentration reliably even when the tidal volume is small. Nevertheless, the new generation of ultrasonic flow meters offers a reasonable alternative to the mass spectrometers and therefore has become widely used in the measurement of MBW.

The calibration of any of the commercial devices requires detailed and age-specific standard operating procedures. Each step of the calibration procedure is crucial for the quality and reliability of the test; therefore it should be performed before each test occasion by experienced examiners.

The time of the measurement varies between individuals and it depends on age, breathing pattern, and disease; however, despite the faster breathing frequency the test is particularly time consuming in infants and young children. The time required for the test is one of the most important key points of MBW, since this will determine the feasibility of the test in young children in a clinical setting. Generally, three reproducible recordings (FRC within 25% in the three tests) are accepted as a complete test. This is usually difficult to achieve in infants and young children for multiple reasons.[154] In unsedated infants, is not always possible to collect all the data within the same sleeping period. At this stage, there are no data available on how the different sleep states affect the results of the test. Additionally, the lack of sedation increases the natural variability of the breathing pattern, which makes it more difficult to fulfill the acceptability criteria in infants. In preschool-age children, their limited attention span makes it challenging to record three acceptable tests in one sitting. It has recently been reported that although MBW was successful in 82% of asthmatic children below 7 years of age,[155] only 15% of the children were able to complete the three trials necessary for a valid test within 20 minutes. Even if the acceptability criteria were modified to two trials, 40% of the children were not able to complete the test within 20 minutes. Success rate was reported to increase significantly with age.[155a] In older children, success rate between 70% and 91% was achieved.[155b] To relax the children and divert their attention from the test, they are usually allowed to watch movies during the testing; however, it increases the risk of a leak around the mouthpiece, and their respiratory rate can also increase if they get too excited about the movie, or it also invalidates the test if they are making noises (e.g., singing) during the test; therefore the movie has to be selected wisely.

Many attempts have been made to decrease the length of the measurements and hence increase the feasibility of the test in young children.[156] New end points of the test have been suggested and examined, such as increasing the end-concentration level of the test gas from 1/40 to 1/20 or stopping the test after a certain number of turnovers such as 6. However, it was shown that these modifications might not influence the specificity of the test (i.e., the discrimination between healthy and diseased study groups remained unchanged) but decrease the sensitivity (i.e., the small differences such as the effect of a treatment disappeared).[156] Also, reading LCI at an end-tidal concentration of 5% (instead of 2.5%)

did not increase the success rate significantly in children and young adults.[155b] In has also been suggested that two measurements can be accepted if they are reproducible (FRC within 10%) as this was shown to have minimal or no effect on the results of the test.

To further increase the feasibility of the test in preschool-age children, a facemask can be used during the test; however, the effect of the different surfaces (of the mouthpiece and the facemask) on the outcome measures of MBW has not been established yet. The use of facemask increases the dead space by a variable amount and it should be corrected for as much as possible in the settings. When a facemask is used, it may be difficult to establish whether the child is breathing through the nose or the mouth. It has also been suggested that the pathway of the breathing (nasal vs. oral) can affect the number of turnovers required for the washout; hence it affects the value of LCI.

One of the main limitations of MBW is the requirement of a stable breathing pattern, which is difficult to achieve in both infants and preschool-age children. Since the calculation of the main outcome measure, LCI, is calculated based on the assumption of a stable FRC and tidal volume throughout the test, any variability in the breathing pattern can make the results of the test unreliable. Furthermore, sighs are frequently present as part of the normal breathing pattern in infants, which can invalidate the test especially if they occur during the washout phase. In this case a new test should be considered.

Further limitations of MBW are the effects of different gases, measurement methods, and algorithms of data analysis that vary not only between commercial devices but also between different hardware and software versions of one given device.[157] The data collected with different gases or with different equipment are not comparable and only reference data collected with the same device, gas, and method can be used for any comparison. This also makes the interpretation of longitudinal studies difficult, as the results from an $SF_6$ washout in infants cannot be directly compared with that from a $N_2$ washout in the same children later in life. Different software algorithms (e.g., the reading of the results at the end of expiration or inspiration, the end-point of the test) also change the results of the test[157]; therefore the standardization of the test is of utmost importance. An ATS/ERS working group has been established to review these issues and standardize the test in preschool-age children. Infant and preschool-age specific acceptability criteria would significantly improve the clinical utility of MBW.

## Potential Clinical Applications in Infants and Children

Since, theoretically, MBW can be performed during tidal breathing in any age group, its application has great potential in the follow-up of chronic respiratory disorders, or early detection of lung disease, that are expected to influence the gas mixing capacity of the respiratory system.

In research studies that aimed to investigate the respiratory health in early life, MBW was performed in both spontaneously breathing and ventilated infants, and most of these studies have focused on the effect of preterm birth on ventilation inhomogeneity (Figs. 11.32 and 11.34).[158–163] As a summary of these studies, preterm babies had reduced ventilation homogeneity[158–163] which improved after the administration of surfactant.[162,163] In healthy neonates and young infants, the degree of ventilation inhomogeneity (i.e., the value of LCI) is highly dependent on the age when LCI is measured, and this makes the evaluation of these tests more difficult. Generally, LCI shows an age-dependent decrease in the first 2 years of life with the highest being in the first days of life (Fig. 11.35),[17] and after the toddler years, the value of LCI plateaus throughout life (until elderly when it starts to increase again). It warrants further investigation whether the age-dependence of LCI in the early years reflects less homogeneous ventilation in infancy, lung development with ongoing alveolarization, or merely the switch between primarily nasal and oral breathing. Note here that although LCI seems to be independent of age, height, and sex between 2 years of age and adulthood, most of the other outcome measures are strongly affected by age. Therefore—similarly to other lung function tests—*z*-scores should be established for both infants and children, and the presentation of raw data at any age group should be reviewed carefully. Short- and long-term reproducibility of LCI has recently been established and 15% change in LCI was defined as clinically relevant change in preschool-aged children.[163a]

In infants and older children reproducibility also requires further research to improve the usefulness of LCI to track respiratory disease.

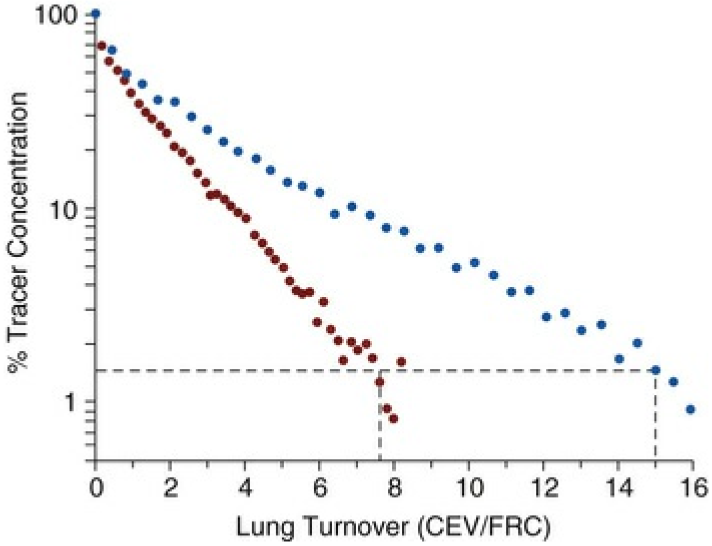

**FIG. 11.34** Tracer concentration as function of lung turnover: Representative graphs of fall in normalized tracer concentration during MBWSF6 washout in term infant *(red circle)* and preterm infant (28 w PMA) at 10 weeks of postnatal age *(blue circle),* demonstrating prolonged tail associated with increased ventilation inhomogeneity. *Dotted lines* show number of turnovers required to reduce tracer gas to 2% of initial tracer concentration (equivalent to lung clearance index, LCI). *CEV,* Cumulative expired volume; *FRC,* functional residual capacity. (Pillow JJ, Frerichs I, Stocks J. Lung function tests in neonates and infants with chronic lung disease: global and regional ventilation inhomogeneity. *Pediatr Pulmonol*. 2006;41(2):105-121.)

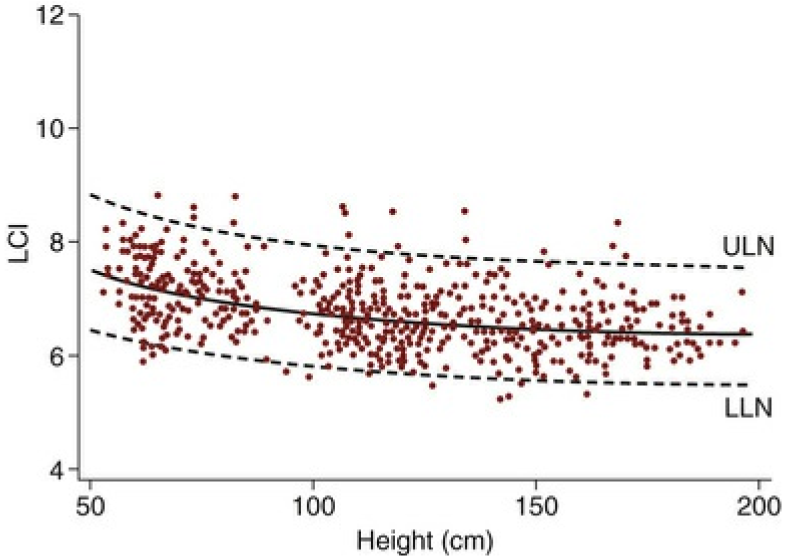

**FIG. 11.35** Lung clearance index (LCI) from infancy to 19 years of age. The solid line denotes the predicted (50th centile) LCI for height and the dashed lines denote the upper limit of normal (ULN; 97.5th centile) and lower limit of normal (LLN; 2.5th centile). (Lum S, Stocks J, Stanojevic S, et al. Age and height dependence of lung clearance index and functional residual capacity. *Eur Respir J*. 2013;41(6):1371-1377.)

The clinical utility of MBW in infants is further limited due to the variability of indices reported in the literature, which can be explained by the home- or custom-made devices used exclusively until very recently. The data reported in these studies are therefore not comparable; hopefully this problem will disappear with the introduction of commercially available devices, standard operating procedures, and large datasets from healthy subjects.

The interpretation of "normal" or "high" LCI values also requires careful consideration, as it has been shown that a normal LCI value does not always reflect a lack of ventilation inhomogeneity, especially in infants. Since MBW only measures the ventilation of the lung units that are in direct communication with the airway opening at the time of the measurement, if there is atelectasis or hyperinflation with air trapping, LCI can still be normal. It is also important to note that in many research studies infants have been sedated for the MBW test, which can also cause atelectasis and air trapping during the test and, hence, false negative results on ventilation inhomogeneity. Therefore it is of utmost importance to interpret the LCI values together with measures of lung volume, clinical data, and imaging (whenever available). Normal LCI values with low FRC can reflect atelectasis, while a normal LCI with high FRC can be a result of airway obstruction with hyperinflation. Although MBW has been shown to have some potential in the detection of airway obstruction, to date no evidence supports the clinical use of this technique in recurrent wheezers or young asthmatics.

One of the main clinical potentials of MBW in both infants and preschool-age children is the early detection of respiratory abnormalities related to CF. Several research studies and clinical observations have suggested that preschool-age children with CF have normal spirometry even when structural alterations in their lungs are already present on the CT scan.[50] The assessment of these early alterations and their longitudinal changes with a technique that does not involve radiation would be of utmost importance for pediatric respiratory physicians. Although early intervention would significantly improve the life expectancy and quality of life of children with CF, it remains difficult to find an objective, sensitive, and specific outcome measure that might be suitable to assess the response to therapeutic interventions. Recent studies have reported promising results in both preschool- and school-age children with CF (Fig. 11.36),[106,164–169] and some of these results were further validated with imaging techniques.[165–168] Therefore LCI was suggested as a potential outcome measure for clinical trials of therapies for CF in young children[51,170] and the first studies have already been set up worldwide. Unfortunately, the results remain less straightforward in infants, since LCI is less discriminative between healthy infants and those with CF, and its value seems to be insensitive to early structural abnormalities detected on the CT scan.[165]

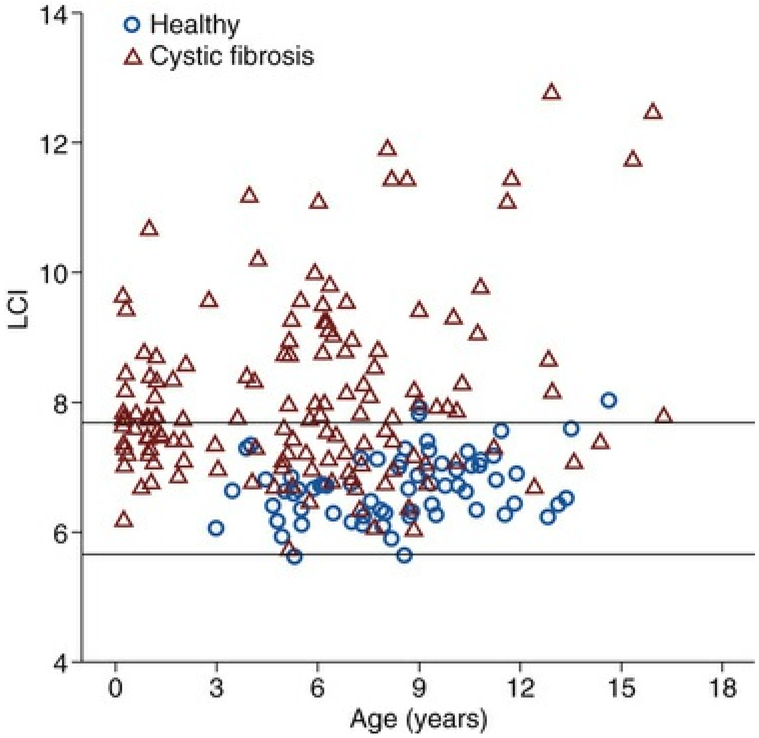

**FIG. 11.36** Lung clearance index (LCI) plotted against age for healthy control children *(circles)* and children with cystic fibrosis *(triangles).* Horizontal lines indicate the upper (7.7) and lower (5.7) limits of normal for LCI. (Ramsey KA, Rosenow T, Turkovic L, et al. Lung Clearance Index and structural lung disease on computed tomography in early cystic fibrosis. *Am J Respir Crit Care Med*. 2016;193(1):60-67.)

Although MBW shows great potential in the detection and longitudinal follow-up of early lung disease, as a consequence of the discussed limitations in infants and preschool-age children, the technique requires further validation and standardization before it is introduced into everyday clinical practice.

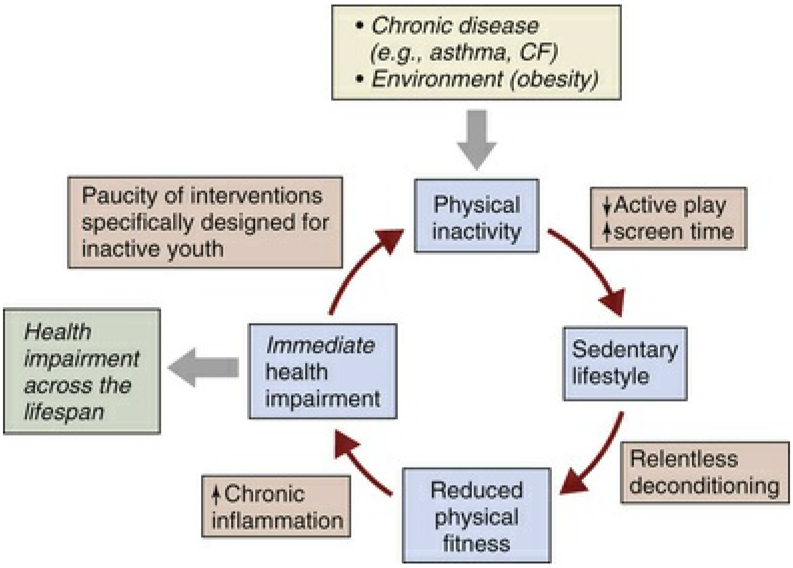
# Exercise and Lung Function in Child Health and Disease

*Dan M. Cooper MD, Ronen Bar-Yoseph MD, J. Tod Olin MD, MSCS, Shlomit Radom-Aizik PhD*

## The Biological Importance of Physical Activity in the Growing Child

Exercise in children and adolescents is not merely play, but is an essential component of growth and development.[1–3] Children are among the most spontaneously physically active human beings.[4] It is not surprising that habitual physical activity (HPA) is a major determinant of health across the lifespan and health-related quality of life in both healthy children and in children with chronic diseases.[5–8] Despite this essential biologic role for HPA, children have not been spared the relentless reduction in levels of physical activity (PA) that is creating a crisis in health care in our nation and throughout the world.[9] Recognition of the enormous morbidity and cost of physical inactivity-related diseases, such as atherosclerosis, type 2 diabetes, and osteoporosis,[10–12] along with the deleterious consequences of physical inactivity and deconditioning in pediatric respiratory diseases like asthma and cystic fibrosis (CF), has spurred new policy initiatives targeting preventive medicine early in life. The concept of pediatric origins of adult health and disease is gaining scientific merit (e.g., chronic obstructive pulmonary disease [COPD]),[13–17] highlighting the need to transform existing notions of how to evaluate health in a growing child. A physically inactive child may have no symptoms of disease, but evidence of deterioration in vascular health may already be present.[18–20] As we move into the era of population health management and precision medicine,[21] the notion of what it means to be a healthy child must change and include robust metrics of physical fitness.

As noted, the deleterious health effects of physical inactivity and poor fitness are exacerbated in children with chronic disease and/or disabilities[22–27] or with environmental-lifestyle conditions like obesity.[28] Children with previously fatal diseases or conditions (e.g., CF, prematurity, acute lymphocytic leukemia) are living longer due to remarkable advances in research and care, but are often unable to achieve levels of PA and fitness associated with health benefits in otherwise healthy children.[27,29–31] Not surprisingly, the *healthspan* (the period of life free from serious chronic diseases and disability[32]) of children with chronic diseases is threatened not only by the underlying disease but by the compounding effects of insufficient PA and sedentary behavior.[33–37] Increasing PA and fitness is feasible, but has proven quite challenging to implement in a systematic manner.[38] Once a pattern of physical inactivity and a sedentary lifestyle is established, a vicious cycle ensues (Fig. 12.1), in which constraints on PA harm immediate health and contribute to lifelong health impairment ranging from cardiovascular and metabolic disease to osteoporosis.[1,39–43] Exactly what constitutes ideal physical fitness in a child with a chronic condition remains unknown. Finding beneficial levels of PA in children with chronic disease or disability is challenging because the optimal range of exercise is much narrower than in a healthy child (Fig. 12.2).



• Chronic disease (e.g., asthma, CF)
• Environment (obesity)
Physical inactivity
↓Active play

Beneficial Exercise
• ↑Cardiovascular health
• Immune cell priming
• Bone mineralization
• ↑Cognitive function
• Improved healthspan
Dangerous Exercise
• Overuse syndrome
• Immune compromise
• Musculoskeletal injury
• Impaired growth

**FIG. 12.2** Health benefits of exercise are determined, in part, by the energy expenditure associated with physical activity. Both too much (excessive) and too little (sedentarism) exercise can impair health. As shown, the range of healthy exercise is narrower in the child with chronic disease or disability. Formal cardiopulmonary exercise testing and field assessments of physical activity can be translated into a well-informed “exercise prescription” for the child with respiratory, cardiovascular, or metabolic diseases. The prescription must specify the mode, frequency,

duration, and intensity of exercise that can benefit health during critical periods of growth.

Change in policy and practice, and the resources necessary to achieve such change, must increasingly be fueled by translational scientific evidence.[44] Despite the broad recognition that many children in the United States (and throughout the world) no longer engage in healthy levels of PA,[45] defining what the level of optimal PA should be remains quite vague. For example, in a recent study of 182, 9–11-year-olds, Füssenich and coworkers[46] noted, *"there were no differences between CCVR [composite cardiovascular risk score] of children who undertook 60 min MVPA [moderate to vigorous physical activity] per day in accordance with WHO recommendations, and those who did not. This implies that current recommendations may be an underestimation of the PA [physical activity] necessary to reduce clustered CVD risk. A gender difference between the CVD risk in active and inactive children raises the possibility that gender specific guidelines may be needed, although much work is needed to determine if these differences are a result of gender specific responses to PA or sex differences in PA level…. Taken together these findings suggest that in order to reduce CVD risk, the current guidelines should be updated…."*

## From the Playground to the Bench to the Physician's Office

### Integrating Laboratory Cardiopulmonary Exercise Testing and Field Assessments of Physical Fitness

Although it might seem intuitive that physically active children and adolescents score well in cardiopulmonary exercise testing (CPET), quantifying the mechanistic relationship between these two components of physical fitness and activity in children and adolescents has proven to be challenging. Only weak correlations between HPA and CPET are consistently found[47,48]; HPA and CPET are not interchangeable physical fitness–associated biomarkers. Traditional CPET focuses on measuring maximal efforts, but as we and others have shown, high-intensity PA occurs relatively infrequently in real lives of children and adolescents[49–51]; thus, even high levels of HPA may not be evident in traditional CPET. Until recently, there has been little standardization of the methodologies used to assess HPA in children, which include a myriad of tools and technologies such as questionnaires, activity logs, HR monitoring, and wearable accelerometers.[52–57] Most practicing primary care child health care providers perceive the overall levels of and participation in daily HPA as a more important indicator of child health than the results of CPET *per se* (if only because formal education in exercise physiology and CPET is lacking in medical school[58] or most residency programs).

Schools and communities are currently investing substantial resources in physical fitness assessments in children; such tests are **mandated** in 46 of 50 states in the fifth, seventh, and ninth grades. In California, testing is done *"to help students in starting life-long habits of regular physical activity."*[59] The school-based tests typically used are the 20 m shuttle run or the mile run. The raw data from these tests are entered into standardized equations to estimate maximal oxygen uptake ($\dot{V}O_{2max}$), but none of the data become part of the child's medical record.

## What Can We Learn From Cardiopulmonary Exercise Testing (Fig. 12.3)

Consider, for example, the important acts of fleeing from a predator or, in more modern terms, running to avoid an oncoming car. When sudden and large increases in metabolic demand are imposed by PA, the whole organism can successfully function only by means of an integrated response among several organ systems. At the very onset of exercise, before there has been sufficient time for an in increase in environmental oxygen uptake, the healthy human must have sufficient stores of oxygen, high-energy phosphates, nonaerobic metabolic capability, and supplies of substrate to perform significant amounts of PA. As exercise proceeds, cardiac output increases and blood flow is diverted to the working muscles without compromising the critical flow of oxygen and glucose to the brain.

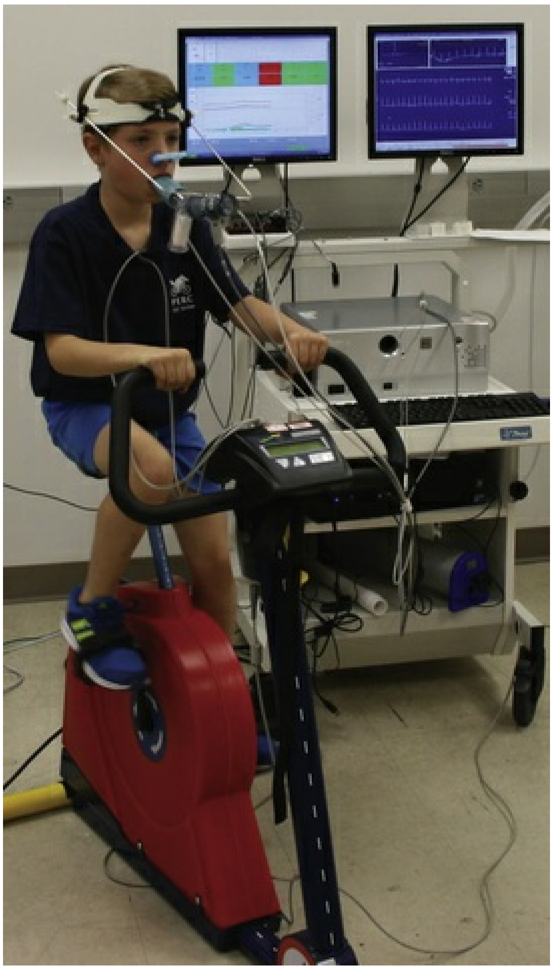

**FIG. 12.3** Eight-year-old boy performing a cardiopulmonary exercise testing in a laboratory setting. Note the cycle ergometer that is designated for young children. Nose clip and mouth piece enable accurate gas exchange measurement during the exercise test.

Ventilation and pulmonary blood flow must increase to precisely match the energy demand of the working muscles so that homeostasis for $PaCO_2$ and pH are maintained. There must be sufficient increase in substrate availability (glucose, fat, protein) but without depleting the peripheral blood glucose stores. And finally, the heat produced during exercise must be dissipated so that homeostasis for body temperature is maintained. In summary, as diagrammed in the late 1960s by Wasserman and coworkers,[60] events at the cell are closely linked to events at the heart and lungs (Fig. 12.4).

Physical fitness and exercise biomarkers are promising "disease-agnostic" tools for a remarkably wide range of health conditions, ranging from asthma in children to COPD in the elderly.[61–64] Exercise testing provides insight into integrated physiological responses that are hidden when the subject is at rest. Despite this promise, exercise-related outcome variables are used far more commonly in the research laboratory than in clinical trials or clinical practice. Poor fitness and low PA are major causes of morbidity and mortality from obesity, cardiovascular disease, type 2 diabetes, chronic respiratory diseases, and some malignancies, but the use of exercise biomarkers in clinical trials is still largely untapped.[65] Consequently, the potential tangible clinical benefits of exercise as a diagnostic and therapeutic tool have failed to fully materialize.

Children are naturally physically active,[66,67] and therefore quantifying physical fitness through formal exercise testing is increasingly useful as a biomarker in a variety of pediatric conditions such as congenital heart disease, sickle cell anemia, athletic training, and cerebral palsy.[68–72] Physiological parameters obtained at maximal or peak exercise (most notably, maximal oxygen uptake-$VO_{2max}$ or peak $VO_2$) remain the most widely used type of exercise laboratory test in pediatric clinical trials and research. As outlined below, true plateaus or reductions in oxygen uptake despite increasing work rate (WR), the hallmark of $\dot{V}O_{2max}$, occur only in a minority of children. CPET is minimally invasive, rendering it suitable for studies in children. CPET is typically performed with cycle ergometers or treadmills, in which the work input increases progressively until the child reaches the limit of his or her tolerance.

Maximal exercise tests are, by definition, highly dependent on the willingness of each child to continue exercise at relatively high WRs when dyspnea, muscle fatigue, and other stress sensations are commonly experienced. Not surprisingly, the “cheerleading” abilities of the laboratory personnel contribute to the achievement of a true maximal response in CPET. Despite its proven clinical and research utility, $\dot{V}O_{2max}$, as noted, only occurs in a minority of exercise tests even in otherwise healthy children and maybe less so in children with chronic disease or disability. For example, in a recent large study of children and adolescents (mean age 12.3 years old) who had undergone the Fontan correction for congenital heart disease during childhood, only 166 of 411 patients (40%) achieved an acceptable $\dot{V}O_{2max}$ using current criteria.[73] This is one reason why many clinicians and researchers choose to use the “peak” $\dot{V}O_2$ rather than $\dot{V}O_{2max}$.

Most modern commercially available CPET devices measure gas exchange variables ($\dot{V}O_2$, carbon dioxide output-$\dot{V}CO_2$, ventilation-$\dot{V}_E$) and heart rate (HR) quite frequently (e.g., breath-by-breath or with mixing chamber gas collection devices in regular intervals multiple times per minute), and these data are collected well before maximal exercise is achieved. Thus, when a child does not reach an exercise level in CPET that can be classified as maximal, the whole test may be deemed a failure despite the wealth of data successfully collected. Such data could shed light on fitness and other specific indicators of cardiac, pulmonary, or metabolic disease even in the absence of a true $\dot{V}O_{2max}$.

## Physiologic Response to Progressive Exercise Testing

A ramp protocol is often used in CPET in adults and children, and is so named because exercise is performed on a cycle ergometer and WR increases linearly in a ramp-type pattern until the participant reaches the limit of his or her tolerance (Fig. 12.5). Gas exchange is typically measured with the use of mouthpieces or facemasks and the many technological advances made over the past several decades in assessing oxygen uptake and carbon dioxide output permit breath-by-breath measurement. HR is measured using standardized monitoring. Armstrong and Fawkner summarized noninvasive methods that are currently used to assess exercise biomarkers in children.[74] It has been particularly useful in developing relatively simple equations to describe the gas exchange and HR responses to the progressive WR exercise protocols that typify CPET. Whipp and coworkers[75] elegantly outlined the theoretical and experimental framework that predicted and demonstrated the largely linear response of $\dot{V}O_2$ to the steady increase in WR during ramp exercise protocols. Their model assumed a system with first-order linear dynamics, an assumption that is accurate for low-intensity exercise. A number of studies have attempted to determine the value of $\tau$ (the time constant for the first-order linear equation) for gas exchange and HR variables in children.[76,77] Factors such as maturational status and the presence of disease and obesity appear to play a role.[26,78] After the initial minutes of the ramp test, $\dot{V}O_2$ approaches a linear increase as the ramp progresses. We do recognize that system dynamics become more complex when exercise is performed at high intensities.[79]

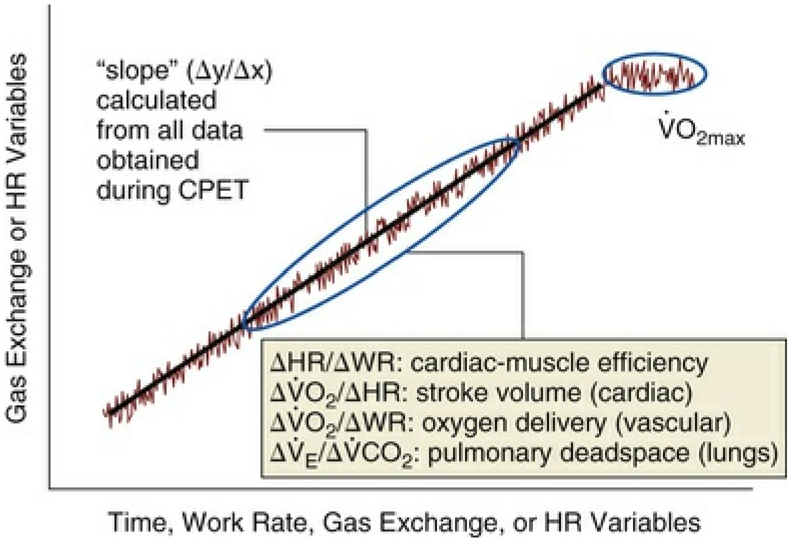

**FIG. 12.5** A schematic generalization of the determination of slopes of key cardiopulmonary exercise testing (CPET) variables from a ramp-type, cycle ergometry, progressive exercise protocol. The classic CPET metric, peak or $\dot{V}O_{2max}$, is shown as the plateau at the end of the test. Unlike the peak $\dot{V}O_2$ or $\dot{V}O_{2max}$, which rely on a relatively small set of data obtained during very heavy exercise, the slopes are derived from a much larger set of data obtained throughout the exercise protocol. As shown, the slopes can serve as noninvasive biomarkers of health and disease providing insights and biomarkers of respiratory and cardiovascular physiology. *HR,* Heart rate.

The anaerobic threshold (AT, also referred to as the "lactate threshold") indicates the point at which excess lactic acid production leads to increases in circulating lactate concentrations and acidosis. Although the mechanism of the AT is not completely clear, one possibility is that at some point during exercise, oxygen supply to the working muscles is inadequate and anaerobic metabolism is necessary to supply the energy requirements of physical work. The AT can be measured directly from blood samples taken during exercise. The onset of anaerobic metabolism is affected by such factors as anemia and the presence of peripheral vascular disease. The ramp protocol and breath-by-breath analysis of gas exchange allow a noninvasive measurement of the ventilatory threshold (a synonym for AT when gas exchange data is used) and $\dot{V}O_{2max}$ in a single exercise test.[75,80] Measuring the AT in children is a potential biomarker of both respiratory and cardiovascular disease,[81] first, because the test is noninvasive, and second, because the protocol is both brief and stimulating to the young child whose sense of competition is high but whose attention span is low. Additional work is needed to examine the maturation of the kinetics of CPET variables during growth and maturation.

The dynamic relationships among gas exchange and HR variables during progressive CPET are promising tools for evaluating fitness in healthy children or in children with chronic disease and disability.[82] The relationship between $\dot{V}_E$ and $\dot{V}CO_2$ is given by a modification of the alveolar gas equation:

$$\dot{V}_E = [863 \times PaCO_2^{-1} \times (1 - V_D/V_T)^{-1}] \times \dot{V}CO_2$$

where $\dot{V}_E$ is ventilation, $\dot{V}CO_2$ is $CO_2$ production, $PaCO_2$ is arterial $CO_2$ tension, and $V_D/V_T$ is deadspace to tidal volume ratio. As can be seen, the factors affecting the relationship between $\dot{V}_E$ and $\dot{V}CO_2$ will be the $PaCO_2$ and the $V_D/V_T$. The equation implies that as the regulated level of $PCO_2$ decreases, more ventilation will be required for a given increase in $\dot{V}CO_2$.

Because ventilation and $CO_2$ production during exercise are determined in large measure by muscle mass (highly related to body mass), $\Delta\dot{V}_E/\Delta\dot{V}CO_2$ should be a body-size–independent CPET variable. However, others and we have noted a weak but significant correlation between $\Delta\dot{V}_E/\Delta\dot{V}CO_2$ and both total body mass (TBM) and lean body mass (LBM). As has been described in greater detail earlier,[83] analysis of the alveolar gas equation indicates that $\Delta\dot{V}_E/\Delta\dot{V}CO_2$ is determined by ventilatory factors such as physiological deadspace, $CO_2$ storage capacity, and the $PaCO_2$ set point (the concentration of $CO_2$ that is homeostatically maintained despite changes in $CO_2$ production). Maturation of each of these factors is reflected by the higher values of the slope in younger children compared with adolescents.[83]

$\Delta\dot{V}_E/\Delta\dot{V}CO_2$ is abnormal in children with chronic lung diseases like CF, in which ventilatory deadspace is known to be increased,[27] and was recently found to be an independent predictor of mortality in adult patients with chronic obstructive pulmonary disease undergoing surgery for nonsmall-cell lung cancer.[84] Thus, analysis of $\Delta \dot{V}_E/\Delta \dot{V}CO_2$ in children with chronic lung diseases may provide specific information about lung function not readily determined from maximal exercise values alone.

## The Challenge of Scaling Cardiopulmonary Exercise Testing to Body Mass in Children and Adolescents and the Special Case of Obesity

Physical fitness and PA are essential components in both the diagnosis and treatment of the overweight and obese child and adolescent.[85–87] Despite this, evidence-based guidelines do not yet exist on how best to assess and track physical fitness in this population. Recently, Hansen and coworkers[88] reviewed a number of studies focused on assessing fitness from CPET in obese adolescents. They were unable to find consensus among these studies, and reached the following conclusion: *"Whether cardiopulmonary anomalies during maximal exercise testing would occur in obese adolescents remains uncertain. Studies are therefore warranted to examine the cardiopulmonary response during maximal exercise testing in obese adolescents."*

Measuring fitness in children (whether normal weight, overweight, or obese) is complicated because muscle and fat mass and hormonal regulation of metabolism and growth change rapidly in children and adolescents.[89–91] Consequently, any physiological variable derived from CPET must be scaled to some index of body size and maturational status. In the obese child, useful scaling of CPET variables is further confounded because body fat (virtually metabolically inactive during exercise) may obscure the effect of the metabolically active muscle tissue when CPET is normalized to body mass.

As noted, maximal exercise tests are highly dependent on the willingness of each child to continue exercise at relatively high WRs. In some cases, investigators purposefully do not exhort obese children during progressive exercise testing. For example, Salvadego and coworkers[92] studied exercise in a group of obese, otherwise healthy adolescents and stopped exercise when the participant achieved a HR of 180 bpm. The authors noted, *"A true maximal test was not performed to avoid the cardiovascular risks associated with maximal exercise in obese subjects."* Further, several studies suggest that obese children and adolescents perceive high-intensity exercise differently than normal-weight controls.[93,94] It is not surprising that the plateau in oxygen uptake, the classical physiologic proof that $\dot{V}O_{2max}$ had been reached, is found in relatively small proportions of normal-weight or obese children and adolescents.[95]

The data from our earlier study of CPET slopes in children and adolescents with body mass index (BMI) below the 85th percentile showed that many of these variables, like peak or maximal $\dot{V}O_2$, were highly correlated with muscle mass.[82] We recently found that both CPET submaximal values and peak $\dot{V}O_2$ were lower in high-BMI adolescents (BMI >95th percentile). We observed this deficiency even after referencing CPET values to LBM. The mechanisms for reduced both peak *and* submaximal CPET results are not entirely clear. Obese children may not push themselves as hard as normal-weight children in the high-intensity range of exercise that typifies peak or maximal $\dot{V}O_2$. Shim and coworkers[94] in obese children with asthma and Marinov and coworkers[96] in otherwise healthy obese children, for example, noted greater sense of breathlessness at high WRs than in normal-BMI children. Salvadego and coworkers[97] showed in a recent elegant study that obese adolescents improved their rate of perceived exertion during high-intensity exercise by reducing the work of breathing (using Heliox).

# Development of Physiological

# Responses to Exercise in Children and Adolescents and Predicting Cardiopulmonary Health Across the Lifespan

With respect to exercise and PA, children are not simply miniature adults.[98] When normalized to body size, strength is lower in children,[99] as is the magnitude of the physiologic response to chronic exercise training (both resistance and aerobic).[100,101] Children use relatively more oxygen than adults for high-intensity exercise.[102] Gas exchange and HR response kinetics are also different in children (Fig. 12.6),[83,103–106] as are metabolic responses such as lactate concentrations,[107] high-energy intramuscular phosphate dynamics (using $^{31}$P-MR spectroscopy[108]), and $CO_2$ storage capacity.[109] Recent work on the genomic responses to exercise in children shows differences in the pattern of leukocyte gene expression between early- and late-pubertal girls.[110] The mechanisms that link the distinct processes of growth and adaptation to exercise are largely unknown.

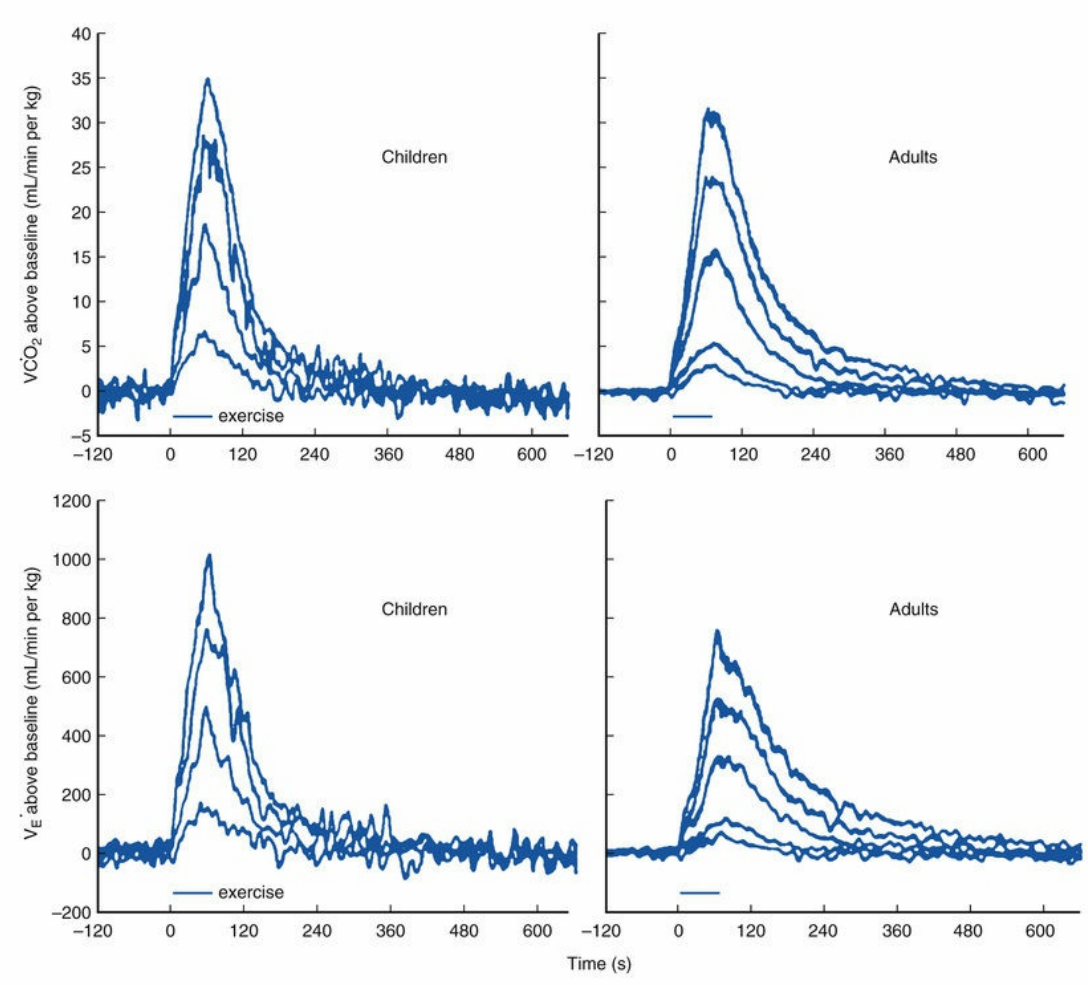

**FIG. 12.6** Examples of differences in physiologic responses to exercise between children and adults. $\dot{V}CO_2$ and $\dot{V}_E$ responses to just 1-min of exercise reveal substantial differences at increasing work intensity (50% of the anaerobic or lactate threshold [AT], 80% of the AT, 75%max, 100%max, and 125%max where maximal exercise (max) was determined from a ramp test previously performed). For both $\dot{V}CO_2$ *(top panel)* and $\dot{V}_E$, the recovery times were substantially faster in the children compared with the adults. (From Armon Y, Cooper DM, Zanconato S. Maturation of ventilatory responses to 1-minute exercise. *Pediatr Res* 1991;29(4 pt 1):362-368.)

A number of pioneering, thoughtfully designed, long-term studies now confirm that cardiovascular disease risk factors begin in youth, track into symptomatic atherosclerosis in adulthood, and are, fortunately, modifiable (e.g., the Muscatine Study,[111] the Young Finns Study,[112] the Bogalusa Heart Study,[113] the CARDIA study,[114] and Pathobiological Determinants of Atherosclerosis in Youth [PDAY][115]). Efforts to develop childhood- and youth-based preventive interventions focused on diet and PA, in combination or separately, have not met expectations. Similar work is needed to determine the long-term effects of pediatric lung disease and the role that exercise and fitness may have in the trajectory of respiratory health across the lifespan.

## Searching for Normal Values in Pediatric Cardiopulmonary Exercise Testing

Resources are needed and in many cases have been mobilized to support the development of drugs and devices focused specifically on children.[116,117] Clinical investigators are increasingly aware of regulatory incentives to perform clinical trials on drugs used specifically for childhood diseases, rather than relying on adult studies. Moreover, clinical researchers understand that effective clinical trials focused on childhood disease must be accompanied by improved laboratory reference standards developed for children.

In a comprehensive review, Shaw and coworkers[118] outlined the challenges facing the development of laboratory reference values in pediatrics. Although focused primarily on blood biomarkers, the following summary provides a relevant framework for establishing normative values in pediatric CPET:

> *Reliable and accurate reference intervals for laboratory analyses are integral for correct interpretation of clinical laboratory test results and therefore for appropriate clinical decision making. Ideally, reference intervals should be established based on a healthy population and stratified for key covariates including age, gender, and ethnicity. However, establishing reference intervals can be challenging as it requires the collection of large numbers of samples from healthy individuals. This challenge is further augmented in*

*pediatrics, where dynamic changes due to child growth and development markedly affect circulating levels of disease biomarkers.*

Mounting literature suggests that fitness (assessed as peak $\dot{V}O_2$) can help predict morbidity and mortality in children.[119] Therefore the development of robust reference values for CPET will serve as a powerful tool in the clinician's ability to (1) identify children in whom the “exercise prescription” might be most beneficial, and (2) assess the success of exercise interventions across the child health spectrum. Of equal importance is the larger public health question of the degree to which fitness and PA levels are decreasing in children and adolescents in the United States and throughout the world and the extent to which these serious threats to health across the lifespan[120] are related to environmental, socioeconomic, and genetic/epigenetic factors. Absent the development of robust CPET normal values, we cannot answer these critically important questions. However, reference values that may be helpful for CPET in children are available.[80,82,121,122]

# Asthma and Exercise

## The Role of Exercise and Physical Activity in Asthma

Despite much recent progress in understanding asthma pathophysiology and the development of new therapies, the health care use associated with asthma and the disruptions it causes to family and community life have not decreased substantially.[123] From the 1990s to the 2000s, asthma prevalence was reported to plateau or even decrease in high-income countries while, in many cases, asthma symptoms became more common.[124,125] At the same time, many low- to middle-income countries with large populations showed increases in prevalence, suggesting that the overall world burden is increasing and nonexpensive strategies are needed to cope with the challenge.[124] Similar to patterns observed in asthma prevalence, children experience higher rates of incident asthma than adults and younger children have higher rates as compared with older children.[126]

The link between PA and asthma is strong, but remains enigmatic. PA is a “double-edged sword” for the child with asthma. On the one hand, PA and exercise is a common trigger of bronchoconstriction, occurring in as many as 90% of asthmatic children and 45% of children with allergic rhinitis.[127–129] Exercise-induced bronchospasm inhibits the ability of affected children to participate normally and perform optimally in physical activities,[128] and it is recognized as an indicator of risk for urgent medical visits.[130] On the other hand, exercise and fitness training seem to benefit asthma control and severity in many children with asthma.[131–134] As succinctly stated by Lucas and Platts-Mills,[135] “It is our belief that an exercise prescription should be part of the treatment for all cases of asthma. The real question is whether prolonged physical activity and, in particular, outdoor play of children play a role in prophylaxis against persistent wheezing. If so, the decrease in physical activity might have played a major role in recent increases in asthma prevalence and severity. The move from traditional lifestyle to urban living can be seen as the progressive loss of a lung-specific protective effect against asthma.”

Critical exercise-asthma treatment issues remain enigmatic and poorly studied, ranging from rare but tragic instances of death due to exercise-induced bronchoconstriction (EIB) in asthmatic youth[136–138] to the lack of clinically validated paradigms of “return to play” following an exercise-associated asthma attack.[139] Despite the accepted clinical goal of ensuring that children with asthma fully participate in all types of exercise, physical fitness and participation in PA have been shown to be impaired in children with asthma.[140–144] Participation in school PE among children with asthma is reported to be reduced by as much as 40%,[145,146] and only 1% of adolescents with asthma and 6% of their teachers gave the correct answer on how to prevent exercise-induced asthma, emphasizing the challenge.[147] Children with asthma were less fit (10% lower $VO_{2max}$) than their peers.[144] Moreover, Conn and coworkers[148] discovered excessive use of electronic media in children with asthma, particularly in those with activity limitation. Studies using accelerometers (a device worn on the body that can measure movement) show equivocal results,[133,149] and Lovstrom and colleagues found that asthmatic patients (10–34 years old) were more frequently physically active and for longer durations than controls.[150] These latter reports can add to the changing prevalence in asthma in recent years. For the inactive asthmatic children, whether this is a result from the perception of disability, parental restrictions,[151] or from poorly managed exercise-associated symptoms is not known. Nevertheless, whatever the causes, reduced participation in PA is an ominous finding in a child with asthma.

There are emerging data, which suggest that exercise is beneficial for asthma in terms of disease control and pathogenesis. A growing number of animal studies (such as those by Pastva and coworkers[152] and Hewitt and coworkers[153]) examined how brief exercise and exercise-training modulated subsequent lung inflammatory responses to ovalbumin (OVA) challenge in OVA-sensitized rats. An intriguing finding from Kodesh and coworkers showed that rats sensitized to OVA were subsequently more susceptible to bronchoconstriction following exercise, a nonspecific challenge.[154] These studies demonstrated a generally moderating effect of exercise on subsequent lung inflammatory responses to acute allergen and exercise challenges, specifically by decreasing nuclear factor κB (NF-κB) nuclear translocation and IκB-$\alpha$ phosphorylation, thereby diminishing key proinflammatory (and possible neuroadrenergic) control pathways. Aerobic training reduced leukocyte activation, reversed airway remodeling, and airway inflammation. Specifically it reversed OVA-induced eosinophil and macrophage airway migration and decreased expression of Th2 cytokines (IL-4, IL-5, IL-13), eotaxin, RANTES, chemokines (CCL5, CCL10), adhesion molecules (VCAM-1, ICAM-1), reactive oxygen and nitrogen species (GP91phox and 3-nitrotyrosine), inducible nitric oxide synthase (iNOS), and NF-κB. It also increased the expression of the antiinflammatory cytokine (IL-10).[155,156] Repeated bouts of moderate-intensity aerobic exercise improve airway hyperresponsiveness (AHR) in OVA-treated mice via a mechanism that involves $\beta_2$-adrenergic receptors.[157]

In children, studies of the benefits of PA and exercise training have yielded similar results. Lung function in children who are more physically active tend to be higher.[143] Aerobic training programs (8–16 weeks) were shown to improve disease control (Asthma Control Questionnaire) and severity (daily doses of inhaled steroids), exercise capacity ($\dot{V}O_{2max}$), reduce pulmonary inflammation (exhaled NO), decrease bronchial hyperresponsiveness (exercise challenge test/methacholine challenge test), and medication use. Lung function ($FEV_1$, FVC) does not change after aerobic training sessions.[131,133,158,159]

Most training sessions include aerobic exercise, and the effect of resistance training on the asthmatic child is yet to be evaluated. Bonsignore and coworkers concluded that exercise training in combination with antiinflammatory therapy might synergize to attenuate airway response to methacholine challenge in asthmatic children.[159] Furthermore, physical inactivity and increased sedentary time were found to predict childhood asthma directly and indirectly (obesity induced).[141,160] Uncontrolled asthma is associated with reduced fitness and daytime spent in intensive activity.[144] Poorly controlled asthma in children contributes to lung disease in adulthood[17]; thus efforts to improve fitness and asthma control in children and adolescents, a "critical period" of growth and development,[161] are bound to have effects on health that last a lifetime. As noted by Ploeger and coworkers,[162] *"To optimize exercise prescriptions and recommendations for patients with a chronic inflammatory disease, more research is needed to define the nature of physical activity that confers health benefits without exacerbating underlying inflammatory stress associated with disease pathology."*

## Exercise-Induced Bronchoconstriction

Exercise-related respiratory symptoms are underdiagnosed and undertreated in many cases and may reflect an isolated clinical condition or uncontrolled underlying asthma.[128] EIB is the acute transient airway narrowing during or after exercise.[163] EIB is defined by the American Thoracic Society (ATS) as percent fall in $FEV_1$ from the preexercise level of >10%–15%, with responses graded as mild, moderate, or severe (10%–25%, 25%–50%, and >50%, respectively).[163] This grading was based on measured values before the widespread use of inhaled steroids; and currently when a child performs an exercise challenge test, $FEV_1$ fall of ≥30% can be graded as "severe." The upper limit of postexercise fall in $FEV_1$ (mean ± 2 SD) in normal children was found to be 6%–8%[164] and higher values for percent fall in $FEV_1$ (13%–15%) have been recommended for diagnosing EIB. Protocols developed by a pioneer in the field, Simon Godfrey, suggest a threshold of $FEV_1$ of ≥13%.[165,166] This threshold was recommended also for preschool children.[167] Other laboratories use a threshold of $FEV_1$ fall of >15% from baseline when testing children to increase sensitivity of the test.[163] Fonseca-Guedes found that FEF25%–75% (postexercise fall >26%) may add to the sensitivity of the test, mainly in children with mild asthma.[168] Symptoms of EIB typically begin after 5–10 minutes of vigorous exercise, peak a few minutes after stopping physical exertion, and usually last for 30–90 minutes.[163] Symptoms may include shortness of breath, dyspnea, chest tightness, coughing, wheezing, decreased performance, increased fatigue, chest pain, and chest tightness.[127,169] In children, the exertional symptoms can be less profound and may include a combination of symptoms.

Obese asthmatic children have a greater exercise-induced fall in $FEV_1$ and a slower recovery from EIB than nonobese asthmatic children, which can limit their participation in physical and sporting activities with peers. Dietary-induced weight loss in overweight and obese asthmatic children leads to significant reduction in severity of EIB and improvement of the quality of life.[170]

## Exercise Challenge Test

An exercise challenge test is usually performed on a treadmill or a cycle ergometer. Most children are more used to walking or running than to cycling, and exercise complaints often appear during running (such as when playing tag, dodge ball, or soccer) (Fig. 12.7).[171] Therefore running is the preferred exercise in children, and can be standardized using a treadmill.[172] ATS and ERS[163,172] guidelines for EIB testing involves a rapid increase in exercise intensity over approximately 2–4 minutes to achieve a high level of ventilation while breathing dry air (<10 mg $H_2O$/L). It should be noted that in adults, breathing dry air enhances EIB and is associated with circulating biomarkers of epithelial damage.[173] The test is performed with a nose clip in place while running or cycling at a load sufficient to raise the HR to ~90% of predicted maximum (predicted maximum HR = 220-age in years) or ventilation to reach ≥17.5–21 times $FEV_1$ (the two most important determinants of EIB are the sustained high level ventilation reached and the water content of the air inspired). Once this level of exercise is attained, the subject should continue exercise at that high level for an additional 4–6 minutes for a total time of 6–8 minutes. These targets are achieved more rapidly with running than cycling. Pulmonary function tests should be measured 5 minutes before the exercise and repeated 1, 3, 5, 10, 15, 20, 30 minutes postexercise; the percent fall in $FEV_1$ compared to baseline is recorded. Nebulized albuterol (salbutamol) or an albuterol inhaler + spacer should be prepared before the exercise test as some children may respond with a severe asthmatic attack. In our lab 200–400 μg albuterol (2–4 puffs of 100 μg) or 0.5 mL of Salbutamol nebulized solution is given to any child immediately after the last pulmonary function test (PFT) done to treat and/or evaluate responsiveness.

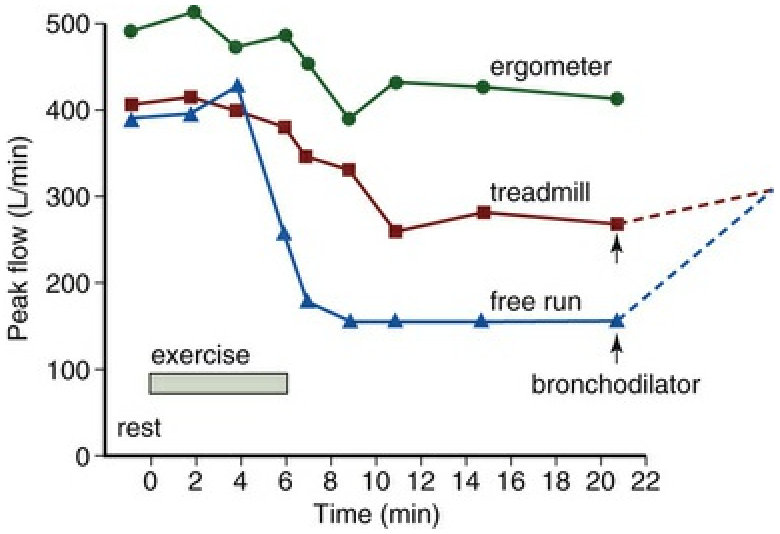

**FIG. 12.7** Response to three types of exercise tests in a healthy 15-year-old boy. Reduction in peak flow was greatest in the field test (free run), less with treadmill testing, and least with the cycle ergometer. (From Anderson SD, Connolly NM, Godfrey S. Comparison of bronchoconstriction induced by cycling and running. *Thorax* 1971;26:396-401.)

It is important to note that the recovery from EIB differs in children compared to adults and in younger compared with older children. For example, Vilozni and coworkers elegantly showed that in very young children (3–6 years old) PFTs should be performed several times during the first 5 minutes after the run due to a very short-lived nadir 2–3 minutes postexercise and that $FEV_{0.5}$ describes the bronchoconstriction event better than the traditional $FEV_1$ (Fig. 12.8).[167] Hofstra and coworkers[174] demonstrated that 7–10-year-olds with EIB improved $FEV_1$ by a mean of 1.60%/min following the challenge, but improvement in 11–12 year-olds was significantly prolonged (0.54%/min). In a group of adolescents, 50% with a positive EIB test showed a maximum postexercise decline at 15 or 30 minutes after exercise cessation[175] and previous reports support this finding.[176] These observations should be taken into account when measuring PFTs after the exercise challenge and when symptoms or complaints indicate a high suspicion of asthma, it is reasonable to measure lung function very early (1–2 minutes postexercise) or late (30 minutes postexercise). Our standard test for demonstrating EIB is either a 6–8-minute run on a treadmill at a speed of 3–5 mph with a slope of 10% or, alternatively, cycle ergometer exercise calculated to achieve about 70% of the child's predicted $VO_{2max}$. This will result in an oxygen consumption of about 60%–80% of $VO_{2max}$ and a HR of 170–180 beats/min.[177,178]

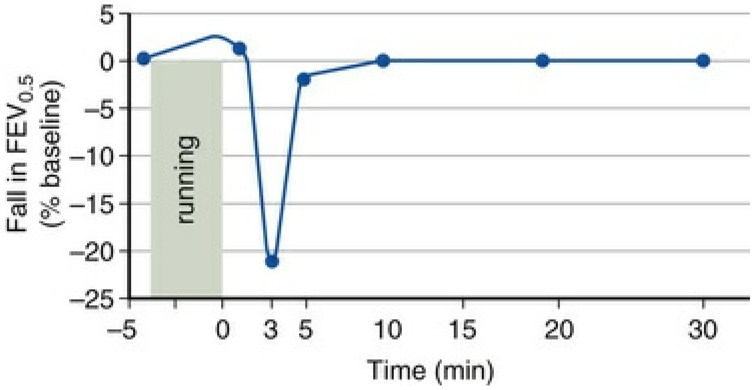

**FIG. 12.8** Exercise-induced bronchoconstriction in preschool children: a representative diagram of the changes in $FEV_{0.5}$ (as a percentage of baseline values) during an exercise challenge test on a treadmill performed by a preschool child. (From Vilozni D, Bentur L, Efrati

O, et al. Exercise challenge test in 3- to 6-year-old asthmatic children. *Chest* 2007;132:497-503.)

## Pretest

Children should avoid PA for at least 4 hours before exercise testing because otherwise they may show an attenuated response due to refractoriness following vigorous repeated exercise. The mechanisms underlying the refractory period are not fully understood but may be due to depletion of catecholamines, prostaglandin release, degranulation of mast cell mediators, and cooling of the airways.[179–181] Medications that can influence the pulmonary response to exercise should be stopped prior to the test: 6 and 12 hours for short- and long-acting beta-adrenergic drugs, respectively; 8 hours for anticholinergic drugs; and 24 hours for cromolyn sodium,[178] leukotriene receptor antagonist (montelukast)[182,183] and nonsteroidal antiinflammatory medications. Recent exposure to inhaled allergens may alter the severity of the response to exercise challenge.[163,179,180,184] Caffeine-containing drinks or food should also be avoided before the test.[185] Inhaled corticosteroids (ICS) are often discontinued 24–48 hours prior to testing, but it is not yet entirely clear whether or not ICS inhibit EIB in the testing context.[181,186] Baseline pulmonary function ($FEV_1$) should be at least 65% of the predicted value.[178] Abrupt cessation of the test or an audible complaint on the part of the patient is suggestive of an alternate diagnosis of deconditioning, upper airway dysfunction, or cardiopulmonary disorders.[187–189] Some studies have shown a higher incidence of EIB in girls while others did not show a sex difference.[175,190]

The diagnosis of asthma in preschool children may be difficult, as these children typically cannot perform reliable spirometric measurement of lung function. Phenomena of wheezing and prolonged expiration appearing and disappearing within 5 minutes after exercise have been described in a group of 3–6-year-old asthmatic children and may have an important clinical application in defining EIB in early childhood, in the absence of spirometry.[167] There are promising new approaches including digitized assessment of recorded breath sounds that may prove useful in years to come in assessing EIB in younger children, a difficult age group to study.[191]

## Exercise and Other Tests for Bronchial Reactivity

Bronchial hyperreactivity to methacholine (MCH) or histamine is a characteristic feature of asthma but is also present in patients with other types of chronic obstructive lung diseases.[164] Positive MCH results showed significantly higher sensitivity and higher positive predictive value in the diagnosis of asthma in children with *postexercise symptoms* than did exercise challenge tests.[164,192] Free-running and sport-specific exercise challenges have been suggested to increase the specificity and sensitivity of exercise challenge test (ECT) in children and young athletes.[193,194] For example, bronchoconstriction associated with a field test (e.g., free run, 6-minute run on a 100 m flat grassed track with nose clip on and continuous heart monitoring) increased the specificity of ECT in children (8–11 years old) for diagnosing asthma, recent wheezing, or atopy to 95%. The sensitivity and specificity were comparable to histamine challenge test.[193] Although field tests may increase ECT sensitivity and specificity, such challenges performed outside the laboratory are difficult to control in terms of exercise intensity and standardizing environmental conditions.[195]

In asthmatic children the severity of EIB may be influenced by the severity of asthma[196] and by preexposure to allergens.[184] Moreover, the severity, duration, and type of exercise may influence the severity of EIB. Running, as compared to swimming under the same inspired air conditions and work intensity, will result in much more EIB.[197]

## The Mechanism of Exercise-Induced Bronchoconstriction Remains Enigmatic

In the widely accepted osmolar hypothesis, dehydration of the airway during hyperventilation of inspired air during exercise leads to a hyperosmolar environment. This environment promotes movement of the water from the airway epithelium, leading to degranulation of mast cells. Mast cell degranulation precipitates the release of mediators such as transglutaminase, which preferentially activates the leukotriene pathway, histamine, and prostaglandin. Release of cellular recruitment factors promotes an influx of inflammatory cells, particularly eosinophils and T cells. The combined impact of mediator releases and influx of inflammatory cells causes bronchoconstriction and inflammation.[189]

There have been extensive studies of the effect of climate on EIB. Breathing warm and humid air during exercise attenuates EIB, but not inevitably,[198] while breathing dry and cold air increases its severity.[199,200] Facial cooling combined with either cold or warm air inhalation causes the greatest EIB, as compared with the isolated challenge with cold air inhalation, a possible vagal effect.[201] Respiratory heat loss (RHL) from the airway mucosa during exercise was suggested by Deal and his colleagues[200] as the trigger for bronchoconstriction, and they showed that exercise and hyperventilation with similar RHL will result in similar bronchoconstriction. Anderson and coworkers showed that epithelial injury in the airways arising from breathing poorly conditioned air at high flows for long periods of time or high volumes with airway hyperemia can obstruct the airway (the "vascular theory").[202]

RHL cannot entirely account for the triggering stimulus for EIB. First, both patients with known asthma and nonaffected controls develop the same degree of RHL during exercise,[203] yet only the patients tend to have EIB. This suggests additional mechanisms that render asthmatics more susceptible (a "second hit" phenomenon). Moreover, as noted, some asthmatic patients will develop EIB while breathing warm humid air at body temperature and humidity, which will not result in RHL.[204] Also, Noviski and his colleagues[205] exercised a group of asthmatic children at two levels of exercise while the respiratory heat and water loss was kept constant by altering the inspired air conditions. They found that the harder exercise with a mean $\dot{V}O_2$ of approximately 1.6 times greater than $\dot{V}O_2$ of the less strenuous exercise resulted in EIB which was greater by almost 1.7 times.

Exercise has been demonstrated to be a vigorous stimulant of the stress/inflammatory immune system[206–209] involving increased levels of circulating IL-6, intracellular adhesion molecules, and increased circulating immune cells, many of which are involved in the pathophysiology of bronchoconstriction.[210] Indeed, given the robust stress/inflammatory response in healthy children along with the increased number of inflammatory cells in the circulation, one might wonder why not all children wheeze when they exercise. Mediator release from circulating leukocytes and/or the airway mast cells was suggested as the intermediary pathway involved in EIB. Leukotrienes $C_4$, $D_4$, and $E_4$ were found in induced sputum and exhaled breath condensate of asthmatic patients with EIB associated with greater desquamation of epithelial cells into the airway lumen.[189] The neutrophil is emerging as a key player early on triggering bronchospasm.[154,211] Preexercise treatment with antagonists of neutrophil-related mediators reduced the severity of EIB and in some reports even prevented EIB refractoriness.[179,212] There is increasing research focused on novel pharmacological agents that would specifically inhibit neutrophil migration and function that may eventually prove to be of benefit in asthma.[213]

## Air Quality, Exercise, and Asthma

As noted by McConnell and coworkers,[214] “Incidence of new diagnoses of asthma is associated with heavy exercise in communities with high concentrations of ozone, thus, air pollution and outdoor exercise could contribute to the development of asthma in children.” Competition or training at areas close to busy roadways, or in indoor ice arenas or chlorinated swimming pools, harbors a risk for acute and chronic airway disorders from high pollutant exposure.[215]

## Exercise-Induced Bronchoconstriction in Nonasthmatics

In recent years, an increasing number of nonasthmatic children (e.g., no asthma diagnosis by a physician and/or negative methacholine/Histamine challenge test) are diagnosed with positive ECT with or without exercise complaints. Up to 50% of Olympic athletes, 29% of adolescent athletes, and 15% of the general pediatric population were reported to have this diagnosis.[175,189,216,217] Most of the data were collected from control children participating in asthma and exercise studies in which they found to have positive ECT or from athletes with/without exercise complaints.

The mechanism suggested for the bronchial responsiveness in nonasthmatic children and athletes is not completely clear but seems to be strongly related to high ventilation rates in cold-dry air; time duration of the exercise challenge may be less important.[218] Other possible mechanisms were suggested in specific circumstances (e.g., ice rink athlete exposure to high-emission pollutants from fossil-fueled ice resurfacing machines, swimmers exposure to chlorine).[195] Airway inflammation was suggested to be involved but the reports are controversial. Some studies reported that nonasthmatic EIB positive athletes have neutrophil-dominant or mixed-type sputum compared to asthmatic EIB-positive patients who have eosinophil dominant inflammation,[219] while other studies on airway inflammation in nonasthmatic EIB-positive athletes have found sputum eosinophilia in a higher percentage compared to asthmatics.[194] Haby and coworkers reported that more than 50% of children with a positive free running exercise challenge had a negative histamine challenge test and concluded that mediators other than histamine may be more important in BHR to exercise or that an additional, nonmast cell mechanism may be involved in BHR to exercise.[193]

In light of the high percentage of exercise complaints in athletes, it was suggested that there may be a different reference range for the drop in $FEV_1$ in elite athletes compared with the general population.[219] One study compared sport/environment specific field-based exercise challenge (cold weather athletes) to a lab-based ECT and concluded that only a 7% drop in $FEV_1$ after treadmill exercise challenge in the laboratory is sufficient to make the diagnosis of EIB compared with a greater drop in $FEV_1$ (e.g., 15%) in a sports-specific setting.[194]

Hallstrand and coworkers studied 256 adolescents participating in organized sports and diagnosed EIB in 9.4% of them. The screening history identified people with symptoms or a previous diagnosis suggestive of EIB in 39.5% of the participants, but only a third of these persons actually had EIB. Among adolescents with a negative review of symptoms of asthma or EIB, 7.8% had EIB. Among adolescents with no previous diagnosis of asthma, allergic rhinitis, or EIB, 7.2% had EIB diagnosed by exercise challenge. Children who screened negative on all questions about symptoms or history of asthma, EIB, and allergic rhinitis accounted for 45.8% of the adolescents with EIB. The authors concluded that "EIB occurs frequently in adolescent athletes, and screening by physical examination and medical history does not accurately detect it."[220] Other studies reported similar findings in athletes.[221]

## Exercise, Asthma, and Bronchoconstriction: Treatment Considerations

The approach to treatment of EIB mainly depends on a preliminary assessment of the isolated clinical condition or uncontrolled underlying asthma with more exercise focused recommendations for the nonasthmatic children and a broader approach including appropriate controller medications for chronic asthma. Therapy should result in optimal control of exercise-induced symptoms during HPA and exercise, and allow unrestricted participation in sports activity in children and athletes.[222] Both nonpharmacological and pharmacological treatment should be discussed in the management plan (Fig. 12.9).[189]

Prevent symptoms
Treat symptoms
• SABAs 5-20 min before exercise (consider addition of MCSA and/or anticholinergic if SABA not working)
• SABAs
• Warm-up exercise
• Face mask or scarf
• Dietary modification
Used daily or more?
• Consider addition of controller therapy (daily ICS+/–LABA, and/or LTRA; antihistamines if allergic)

**FIG. 12.9** ATS algorithm for diagnosis and treatment of exercise-induced bronchoconstriction. *EIB,* Exercise-induced bronchoconstriction; *ICS,* inhaled corticosteroid; *LABA,* long acting $\beta_2$-agonist; *LTRA,* leukotriene receptor antagonist; *MCSA,* mast cell stabilizing agent; *SABA,* short-acting $\beta_2$-agonist. ## Nonpharmacological Approaches

HPA[135,141] and aerobic training[131,159] should be encouraged for treatment and prophylaxis of EIB. Children tend to play in short exercise bouts (up to 1–2 minutes),[50,51] and repeated exercise bouts may increase the threshold for triggering bronchospasm and decrease EIB response.[223] Swimming is less likely to trigger EIB than running.[223] Recommendations should include 1 hour of moderate-vigorous exercise per day and to be as active as possible the rest of the time. Preexercise warm-up is recommended for all patients to attenuate the fall in $FEV_1$ postexercise. Similar results were found whether high-intensity interval or variable intensity warm-up exercise was performed.[163,181] Screen time was found to correlate with activity limitation in children with asthma.[224] Daily screen time should be limited to no more than 2 hours/day and children should be as active as possible during that period.

There is evidence to support a beneficial role for diet in mitigating EIB as well. The most salient example of this is the rare but life-threatening phenomenon of exercise-induced anaphylaxis, which occurs when an individual with a food allergy (often unknown to the patient) engages in exercise several hours following a meal with the offending dietary element.[225] It has been postulated that the mechanism for exercise-induced anaphylaxis in this instance results from the exercise-associated release (perhaps, by catecholamines) into the peripheral circulation of immune cells in the spleen and GALT (gut associated lymphoid tissue) that were locally activated by the ingestion of the food allergen prior to the exercise bout.

Increased intake of natural foods, particularly fresh fruit, vegetables, and oily fish, and decreased salt consumption are the most promising strategies to improve pulmonary function to below the clinical threshold for the diagnosis of EIB.[226] High doses of caffeine (6–9 mg/kg) were shown to provide a significant protective effect against EIB (no significant difference from preexercise $\beta_2$-agonist alone) in a group of adolescent-young adults.[163,227] Reduction in susceptibility to EIB is yet another reason that overweight and obese children should be encouraged to modify dietary intake to gradually decrease body weight.[228] Lower levels of vitamin D are associated with increased reactivity to exercise,[229] and more studies are needed to evaluate the role of vitamin D in EIB management. Ascorbic acid (vitamin C) supplementation may provide a protective effect against exercise-induced airway narrowing. A 50% reduction in the postexercise $FEV_1$ drop and EIB-related symptoms were reported in small groups of adolescent–young adult asthmatic subjects[185,230]; other studies did not find strong correlation between vitamin C and self-reported wheezing.[231] A Cochrane analysis concluded that evidence is not available to provide a robust assessment on the use of vitamin C in the management of asthma or EIB.[232]

Wearing a mask or scarf in cold weather for those with cold weather–EIB offers considerable protection against bronchospasm induced by cold air.[163,189,233] In young adults, combining a $\beta_2$-agonist with a face mask prevented EIB and was superior to treatment with $\beta_2$-agonist or a face mask alone.[233] Breathing through the nose to humidify and warm the inhaled air is suggested to decrease the amount of thermal and moisture loss during exercise.[234]

## Pharmacological Approaches

Prophylactic intermittent treatment (10–15 minutes preexercise) with short-acting bronchodilators is the most commonly used treatment for EIB. $\beta_2$-agonists, both short-acting $\beta_2$-agonist (SABA) and long-acting $\beta_2$-agonist (LABA), when administered preexercise in a single dose, are effective and safe in preventing the symptoms of EIB. Longer-term administration of inhaled $\beta_2$-agonists induces tolerance and lacks sufficient safety data and is not recommended as a single therapy.[163,235] A daily administration of a leukotriene receptor antagonist to ameliorate EIB is also recommended.[163] A single-dose of montelukast was shown to attenuate EIB 1–24 hours after consumption,[183,236] although it is less effective than $\beta_2$-agonists (albuterol) for prevention of EIB in children with asthma.[159] Tolerance to the protective effect of $\beta_2$-agonist does not develop with regular use of montelukast and if breakthrough EIB occurs, a $\beta_2$-agonist can be used effectively as rescue medication. Montelukast treatment added to aerobic training in asthmatic children may exert beneficial effects on BHR.[159]

For daily or frequent EIB complaints, daily administration of an ICS is recommended. It may take 2–4 weeks after the initiation of therapy to see maximal improvement. Administration of ICS only before exercise (“as needed”) is not recommended.[222] EIB is one of the earliest signs of chronic asthma and one of the last symptoms to disappear upon treatment with ICS (Fig. 12.10).[237] In a double-blind, randomized, placebo-controlled trial, intranasal corticosteroid (fluticasone furoate) reduced EIB in asthmatic children with allergic rhinitis.[238] If EIB symptoms are not controlled with regular use of ICS, a LABA or montelukast is recommended.[222] A multimodal treatment concept including physical training and medical treatment with an inhaled steroid for 7 days resulted in a decrease in airway hyperresponsiveness to exercise in children (13.5 ± 2.7 [SD] years). Adding montelukast to the treatment protocol resulted in a further decrease in airway hyperresponsiveness.[239] Chronic treatment with a combination of inhaled corticosteroid and LABA (fluticasone propionate/salmeterol) was shown to provide superior protection compared with an inhaled corticosteroid alone (fluticasone propionate) in protecting against EIB in children with persistent asthma.[240] To date, most of the treatment recommendations are the same between EIB positive asthmatic and EIB positive nonasthmatics. Specific irritants (e.g., cold weather, pollutants, chlorine) should be avoided if possible. It was reported that athletes with positive EIB may compete successfully at the international level despite their symptoms.[189,194]

# Physical Activity, Exercise and Cystic Fibrosis

Recommendations for PA are already part of regular outpatient care offered to most CF patients, sparked by the groundbreaking study of Nixon and coworkers in the New England Journal of Medicine.[241] HPA should be considered as a "vital sign" for health in children and is a key factor for mental health and social life in health and chronic conditions. CF patients are less active than their healthy peers even in those with good lung function, and overall PA declines with age, similar to healthy populations.[241–243] High activity levels in CF patients (12–40 years old) have been linked to improved exercise capacity[243–245] and exercise prescriptions that detailed specific ways to increase HPA improved exercise capacity as well.[244] An increase in HPA was associated with a slower rate of decline in $FEV_1$ in pediatric CF patients (7–17 years old).[246,247] Physical inactivity is a factor significantly contributing to skeletal muscle force in adults with CF.[248] Duration and intensity of daily PA were positively correlated with bone mineral density (BMD) in adolescents and adults with CF and shown to be predictors of BMD Z score.[243]

Gender differences have been reported in habitual activity of CF patients. Girls were less active, but only after the onset of puberty, and pancreatic insufficiency had an impact on measures of fitness and habitual activity that was greatest in late pubertal females.[247,249] A recent statement by the Exercise Working Group European CF Society emphasized the importance of monitoring HPA. It recommended that "activity monitors such as SenseWear or ActiGraph offer informed choices to facilitate a comprehensive assessment of physical activity, and should as a minimum report on dimensions of physical activity including energy expenditure, step count and time spent in different intensities and sedentary time."[242]

Pediatric CF patients were shown to have decreased exercise capacity[27,250]; girls have lower values than boys,[251] and early pubertal have higher values than adolescents.[252] Most CF patients present an annual deterioration in peak $\dot{V}O_2$ (2.1 mL/min/kg per year), and risk factors for deterioration were adolescence, high IgG levels, chronic infection with *P. aeruginosa*, $FEV_1 < 80\%$, and rapid rate of $FEV_1$ deterioration.[252,253] Exercise capacity (peak $\dot{V}O_2$) has been negatively related to morbidity (rate of hospitalization, total IgG levels, chronic infection with *Pseudomonas aeruginosa*),[252,254] quality of life,[255] and mortality[241] in CF patients (Fig. 12.11). Pianosi and coworkers studied 28 CF patients (8–17 years old) with CF who performed annual pulmonary function and maximal exercise tests over a 5-year period to determine $FEV_1$ and peak $\dot{V}O_2$, the magnitude of their change over time, and survival over the subsequent 7–8 years. Peak $\dot{V}O_2$ fell during the observation period in 70% of the patients, with a mean annual decline of 2.1 mL/min per kg. Initial peak $\dot{V}O_2$ was not predictive of rate of decline or mortality, but rate of decline and final peak $\dot{V}O_2$ of the series were significant predictors. Patients with peak $\dot{V}O_2$ less than 32 mL/min per kg exhibited a dramatic increase in mortality, in contrast to those whose peak $\dot{V}O_2$ exceeded 45 mL/min per kg, none of whom died. The first, last, and rate of decline in $FEV_1$ over time were all significant predictors of mortality.[254]

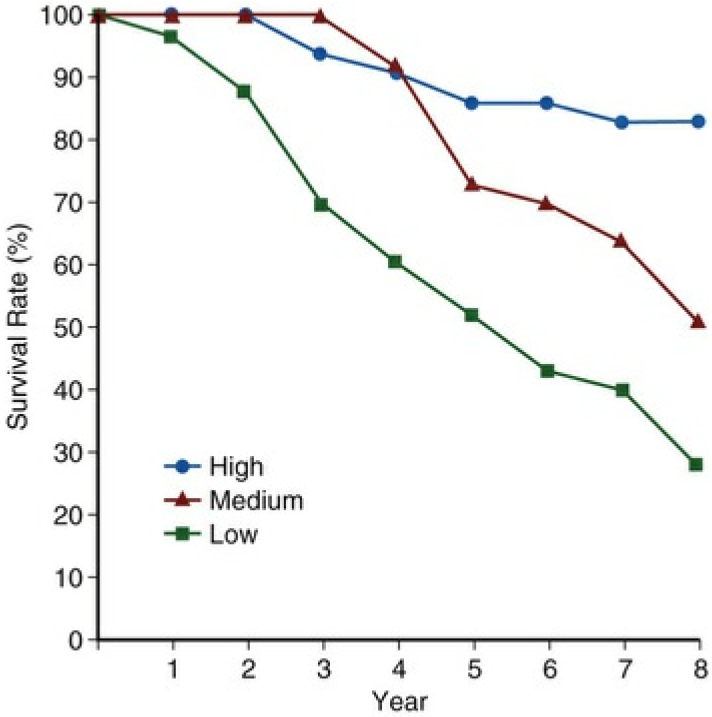

**FIG. 12.11** Survival among 109 cystic fibrosis patients (mean age 17 years old) according to fitness levels

(peak $\dot{V}O_2$). (From Nixon PA, Orenstein DM, Kelsey SF, Doershuk CF. The prognostic value of exercise testing in patients with cystic fibrosis. *NEJM* 1992;327:1785-1788.)

Besides $\dot{V}O_{2max}$ or peak $\dot{V}O_2$, additional submaximal gas exchange measurements (e.g., $\dot{V}_E/\dot{V}CO_2$-slope and $\Delta\dot{V}O_2/\Delta HR$-slope) that do not rely on achievement of maximal effort have a diagnostic potential that is important, especially in children with chronic conditions as CF. As shown in healthy children,[256] slopes can predict maximal values with very good correlations and should be used more often in exercise testing of pediatric CF patients. For example, a model consisting of BMI, $FEV_1$% predicted, and $\dot{V}_E/\dot{V}O_2$ was found to be a strong predictor of mortality rate in adolescents with CF[257] or delayed $\dot{V}O_2$ response time, and $\Delta\dot{V}O_2/\Delta WR$ was suggested to be useful to detect impairment in oxygen transport and oxygen utilization in young patients with CF.[258] $\dot{V}_E/\dot{V}CO_2$, as a marker of ventilation response, was shown to better determine exercise limitation in mild-to-moderate lung disease.[259] Other submaximal tests have been described for evaluating exercise capacity in CF such as the 3-minute step test; HR during and after a 3-minute step test may reflect $\dot{V}O_2$ peak in children with CF.[260]

Several factors might contribute to the reduction in exercise capacity in CF:

1. *Peripheral (muscle) limitation:* Several mechanisms provide some insight that muscle mass and muscle metabolism contribute to exercise intolerance in CF. A defect in sarcoplasmic reticulum CFTR Cl channels could alter the electrochemical gradient, causing dysregulation of Ca homeostasis, essential to excitation-contraction coupling and leading to exercise intolerance and muscle weakness.[261] In another study, impairment in oxygen transport and oxygen utilization by the muscles was described in addition to exercise limitation that was significant just for peak $\dot{V}O_2$ normalized for fat free mass (FFM).[258]
2. *Respiratory limitation:* Peak $\dot{V}O_2$ is correlated with $FEV_1$ during childhood in CF patients.[253,262] Exercise limitation is

not primarily limited by respiratory factors in young patients and in mild CF lung disease (peak $\dot{V}O_2$ remains stable or rises slightly over time in younger patients), while it shows a downward trend in older children with CF, particularly once $FEV_1$ falls below 80% predicted.[262,263] Exercise limitation in adult CF patients is largely dependent on the magnitude of the ventilatory response (reduced or absent breathing reserve and $\dot{V}_E/\dot{V}CO_2$) in patients with mild-to-moderate lung disease, and on $FEV_1$ in patients with severe lung disease.[259] In children, Bongers and coworkers found exaggerated, but adequate, ventilatory response to exercise for $\dot{V}CO_2$ and higher ventilatory demand during submaximal exercise in CF patients with mild-to-moderate airway obstruction.[264] For some exercise-derived parameters it is suggested to use a disease-specific approach. For example, maximal voluntary ventilation (MVV) may be determined directly or indirectly from pulmonary function data, using the functions $MVV = (FEV_1) \times 35$. In CF patients, MVV is expressed as $MVV = 27.7 \times (FEV_1) + 8.8 \times \text{Pred}(FEV_1)$ ($R^2 = 0.98$, $P < .05$).[265]

3. *Genotype:* The class of CFTR mutation correlates with aerobic capacity and peak anaerobic power. Patients with mutations causing defective CFTR production or processing (class I or II) had a significantly lower peak aerobic capacity than those with a mutation conferring defective regulation of CFTR (class III). The peak anaerobic power in subjects with mutations inducing decreased CFTR conduction (class IV) or CFTR mRNA (class V) were significantly higher than children with class I, II, or III mutations.[266] Two studies failed to show any association between genotype or polymorphism and peak $\dot{V}O_2$.[252,267] The presence of CFTR at the sarcoplasmic reticulum of skeletal muscle of CF patients may partly explain genotype/phenotype differences in exercise capacity of patients.[261] However, the relationship between genotype and exercise capacity remains unclear.
4. *Training and deconditioning:* Aerobic training has been repeatedly shown to improve peak aerobic capacity (peak

$\dot{V}O_2$),[244,268] and increases in exercise capacity result in significantly improved lung function and habitual activity.[269] Anaerobic training has measurable effects on aerobic performance, anaerobic performance, and health-related quality of life in children with CF.[270] Resistance training was shown to increase strength, exercise capacity, and work capacity.[271] The beneficial effects of exercise and training in CF patients could be partially explained by blockage of amiloride-sensitive sodium conductance in the respiratory epithelium in response to moderate-intensity exercise. The inhibition of luminal sodium conductance could increase water content of the mucus in the CF lung during exercise.[272]

Responsiveness to exercise training is similar in CF patients and in healthy untrained people regardless of disease severity. Higher improvements in exercise parameters were noted in subjects with lower initial fitness levels.[273] Training programs mainly include a combination of aerobic exercise and resistance and have been reported to have very high adherence (>95%) for 6–8 week sessions[274,275] and 85% for year sessions.[271] This combination may offer multiple important advantages such as improvement in exercise capacity, quality of life (aerobic training), better weight gain (total mass, as well as % fat and fat-free mass), lung function, and leg strength (resistance training).[268,271,275] Short-term (8 weeks) combined aerobic and resistance training program performed in a hospital setting induces significant benefits in the cardiorespiratory fitness and muscle strength of children with CF.[274]

A relatively new training strategy in health and chronic conditions is the high-intensity interval training (HIIT). HIIT includes short (e.g., 10–30 seconds) high-intensity exercise bouts with rest periods in between (e.g., 60–120 seconds). The total amount of work is usually less than a constant aerobic session and total time of training is shorter. A relative short period of HIIT (6 weeks) for a patient with CF with a ventilatory limitation resulted in peak $\dot{V}O_2$ and peak workload increased by 19% and 16%, respectively; there was a rise in peak ventilation by 50% (50–75 L/min), with an increase in both breathing depth and respiratory rate. HIIT should be considered as one of the potential training regimens due to its effectiveness and efficiency, especially in CF patients with a ventilatory limitation and a high treatment burden.[276] Training using interactive gaming consoles represents high-intensity exercise for children and young adults with CF and may be a suitable alternative to conventional exercise modalities.[277] Female patients had lower exercise tolerance than males. Pulmonary function, respiratory rate, and tidal volume did not differ between sexes. Male and female patients, irrespective of disease severity, utilized similar proportions of their ventilatory capacity at exhaustion.[251] Physical exercise in low-inflammation/infection status (e.g., at a young age) should be encouraged. It was reported that chronic systemic inflammation and infection (high total IgG levels and *P. aeruginosa* colonization) leads to negative effects on skeletal muscles, preventing skeletal muscle tissue from improving with regular physical exercise.[252]

It is noteworthy that despite causing significant acute bronchodilation, inhaled albuterol did not improve maximal exercise performance in ventilatory-limited CF adults, adding to the body of literature that fails to show any clinical benefit of SABAs in CF subjects.[278] Further study is needed to better understand the role of SABAs in CF patients.

## Safety

Exercise testing and training is safe in patients with CF. A survey study was conducted in Germany and 78/107 CF centers caring for 4208 patients responded with 256 patients answering a web-based survey. No serious adverse events were reported for 713 exercise tests. With in-hospital training, the yearly incidence of exercise-related serious adverse events such as pneumothorax, cardiac arrhythmia, injury, or hypoglycemia was less than 1% each.[279]

In summary, a recent Cochrane review regarding exercise training in CF including young children and young adults concluded as follows: “Although improvements are not consistent between studies and ranged from no effects to clearly positive effects, the most consistent effects of the heterogeneous exercise training modalities and durations were found for maximal aerobic exercise capacity with unclear effects on $FEV_1$ and health-related quality of life. … Exercise training is already part of regular outpatient care offered to most people with cystic fibrosis, and since there is some evidence for beneficial effects on aerobic fitness and no negative side effects exist, there is no reason to actively discourage this."[280]

### Recommendations

Exercise prescription should be personalized to each patient. In mild-to-moderate CF lung disease, the current guidelines for PA for healthy children (one hour of moderate-vigorous intensity exercise per day) should be the basis for exercise advice in CF patients. With increasing disease severity, a more considered approach to exercise programs is required, incorporating more interval-type training with frequent reevaluation.[281]

## Physical Activity, Exercise, and Lung Disease of Prematurity

Despite remarkable improvements in survivorship of prematurely born babies, the incidence of lung disease and other developmental abnormalities remains a considerable challenge for pediatricians.[282] Results from studies reporting PA levels in children born premature are controversial. A recent study[283] showed a small difference in objectively measured moderate to vigorous PA (MVPA by accelerometry) in 7-year-old children born less than 32 weeks' gestation. Proulx and coworkers reported that 80% of adolescents (16.1 ± 2.5 years old, born ≤29 weeks gestation) did not meet MVPA guidelines (using accelerometry). Risk factors for inactivity were older age, female gender, additional health problems, and marked movement difficulties.[284] However, other studies have not shown the same effect on children and adolescents (8–18 years old).[285,286] Physically fit individuals lose the association between birth weight and metabolic disease, and the association between low birth weight and metabolic syndrome is accentuated in unfit individuals. PA intervention studies indicate that most cardiometabolic risk factors respond to exercise in a protective manner, independent of birth weight.[287]

## Exercise Capacity

Extremely preterm (gestational age of <25 weeks) birth and early preterm (gestational age of <32 weeks) birth were associated with a significant reduction in peak $\dot{V}O_2$ in school-aged children (8–11 years old) compared to full-term controls. These findings were not explained by differences in physical cardiopulmonary factors, or activity levels, but were best predicted by lean body mass. Ventilation did not limit exercise performance, although it appears that breathing during exercise is regulated differently in prematurely born children compared to term-born children and may reflect a long-term pathophysiological impact of EP birth. Postnatal corticosteroids had no effect on aerobic fitness or HPA.[286,288,289] Clemm and coworkers reported contrary findings. Children 10 and 17 years old born preterm (<28 weeks of gestational age) achieved normal exercise capacity, and their response to physical training was comparable to peers born at term. Neonatal BPD and current $FEV_1$ were unrelated to exercise capacity.[290]

In young adults born with a gestational age of less than 32 weeks, a birth weight less than 1500 g, or both factors, preterm birth was associated with lower $FEV_1$, peak WR and AT, but no differences were found in peak $\dot{V}O_2$, and breathing reserve compared to a full-term control group. Again, there were no significant differences in lung function and exercise parameters between preterms with and without BPD. Exercise-induced arterial hypoxemia was not found to contribute to the reduction in aerobic exercise capacity. Severe dyspnea and leg discomfort associated with critical constraints on tidal volume expansion may lead to reduced exercise capacity despite differences in expiratory flow limitation and BPD history, similar to patients with chronic obstructive pulmonary disease.[291–294] Submaximal tests are frequently used in the pediatric population to estimate exercise capacity. No difference was found in submaximal exercise capacity (six-minute walking distance) between school-age subjects (born mean 27 weeks of gestational age) with and without a diagnosis of bronchopulmonary dysplasia (BPD) and controls.[295] However, Tsopanoglou reported that children born prematurely with very low birth weight (<1500 g, mean 30 weeks of gestational age), especially those who had BPD, demonstrated limited functional capacity during submaximal exercise (6-minute walking distance).[296]

In conclusion, PA and exercise, as recommended for healthy children, should be recommended for children who survive prematurity. Potential exercise and health benefits could be achieved by increasing PA levels and exercise training.

## Exercise at Altitude in Child Health

The environment plays a key factor in determining a child's exercise performance and limitations.

Worldwide, it is estimated that >140 million people live at a high altitude (HA), defined as greater than 2500 m (8200 ft.), and millions are visiting HA areas for short periods every year.[297] HA environments pose a number of unique physiological challenges to the child's body, such as lower ambient temperatures, reduced humidity, and lower barometric pressures. To understand the effect of these changes, the "alveolar air equation" can be used:

$$P_AO_2 = P_IO_2 - (P_ACO_2/R)$$

where:

- $P_AO_2$ = Alveolar pressure of oxygen.
- $P_IO_2$ = Partial pressure of oxygen inhaled = $F_IO_2$ X (PB-$P_{H2O}$).
- $F_IO_2$ = The fraction of oxygen in the inspired gas.
- PB = Barometric Pressure.
- $P_{H2O}$ = Partial pressure of water vapor (at body temperature of 37°C).
- $P_ACO_2$ = Alveolar pressure of carbon dioxide = ~40 mmHg (usually kept in a narrow range).

- ■ R (Respiratory Exchange Ratio) = $\dot{V}CO_2/\dot{V}O_2$ ($O_2$ uptake/$CO_2$ exhaled) ~0.8 at rest (>0.8 during intense exercise).

At sea level (at rest): $P_IO_2 = 0.2093 \times (760-47) = 150$ mmHg and $P_AO_2 = 150 - (40/0.8) = 100$ mmHg.

At HA (at rest): $P_IO_2$ decreases because of the decrease in PB while $F_IO_2$ and $P_{H2O}$ stays constant. $P_AO_2$ decreases respectively and $P_aO_2$ as well. For example, at La-Paz, Bolivia (at rest), altitude of ~3700 m, PB = 490 $_{mmHg}$ → $P_IO_2 = 0.2093 \times (490-47) = 93$ $_{mmHg}$ and $P_AO_2 = 93 - (40/0.8) = 43$ $_{mmHg}$ (correlates to $SpO_2$ = ~80%). $P_AO_2$ decreases as does $P_aO_2$ leading to decreased $SpO_2$ (oxygen saturation as percent). The reduced saturation is accompanied by a robust ventilatory response that can lead to true hyperventilation (reduced $P_ACO_2$, $P_aCO_2$, and pH). Not surprisingly, exercise performance at altitude is initially reduced.[298,299] The lower value of $P_aCO_2$ can cause respiratory alkalosis and shifting of the oxyhemoglobin dissociation curve to the left which, paradoxically, might exacerbate the decreased $SpO_2$. These effects, however, are partially compensated for by the increased $\dot{V}_E$ with accompanying elevations in $P_AO_2$, $P_aO_2$. The net effect is a higher $SpO_2$ than might be expected for a certain $P_aO_2$. These are normal physiologic acute responses to HA, and most individuals note a sensation of breathlessness.[300] Acclimatization does occur over time, but our understanding of these mechanisms in children is, at best, incomplete.[301,302]

In children, Major and coworkers reported a mean $SpO_2$ of 87% for adolescent children (16–19 years old) at 3450 m.[303] Children exposed acutely to HA are more sensitive to hypobaric hypoxia than their parents and decrease $SpO_2$ to lower levels.[304,305] Sushi and coworkers conducted a systemic review and reported $SpO_2$ of 0–5-year-olds at greater than 2500 m measured in several studies. The $SpO_2$ depended on the altitude and ranged from 93% at 2600 m to 88% at 4000 m.[306] From their extensive review of the literature in children, Subhi and coworkers concluded, *"Above altitudes of 2500 m, giving oxygen for $SpO_2$ less than 90% may be too liberal for facilities with limited oxygen supplies. There is evidence that for altitudes greater than 2500 m a threshold of $SpO_2$ of 85% can be used to identify children most in need of oxygen. A balance needs to be achieved between using accurate altitude-specific definitions of hypoxemia, and ensuring simple and safe indications for oxygen that can be taught to and used by health workers."*

When reviewing the effect of HA on exercise performance it was shown that $\dot{V}O_{2max}$ is decreased by ~20% when comparing near sea level (~450 m) to 3500 m in young children and adolescents[304] and up to 45% when young adults ascend from sea level to 5260 m.[307] The same effect continues as the adolescents exercise at increasing altitudes (3700–4300 m).[308] Moderate altitude also decreased significantly 3000 m race results in young adults (sea level vs. 2100 m).[299]

Two main mechanisms are involved in the reduction of exercise performance: (1) arterial oxyhemoglobin saturation ($SaO_2$) during maximal exercise and (2) the ratio of lung diffusing capacity to $\dot{V}O_{2max}$.[299] During exercise at HA the capillary transient time of the red blood cell at the alveoli is shorter and the time to complete diffusion is reduced. The ventilatory response is no longer sufficient to prevent arterial oxygen desaturation with exercise (as in most cases at sea level), and the result is a further decrease in $PaO_2$ and $SpO_2$, and the extent of the decrease is dependent upon the exercise intensity.[303,304,309]

Another possible limiting mechanism could be changes in the peripheral muscle. Calbet and colleagues studied young adults exercising at sea level and after 9 weeks at 5260 m and concluded that the major limiting factor to muscle performance at HA was oxygen delivery and not intrinsic peripheral factors.[307] Several studies have confirmed a strong positive relationship between maximal oxygen uptake ($\dot{V}O_{2max}$) at sea level and the magnitude of the decline in $\dot{V}O_{2max}$ at altitude in young adults (the more "fit" on sea level the higher the decline in $\dot{V}O_{2max}$ at altitude).[299,310,311] Chen and coworkers showed that exposure to HA from birth to adolescence resulted in a higher $SpO_2$ at peak $\dot{V}O_2$ and a greater aerobic exercise performance compared to adolescents acclimatized to HA. This may reflect adaptation to life at HA.[308] Cardiorespiratory adaptation to altitude seems to be at least partly hereditary.[304]

# High Altitude and Children With Chronic Lung Disease

The data regarding the effect of HA on chronic conditions in children is scarce.

## Asthma

Environmental factors play an important role on disease symptoms and pathophysiologic mechanisms. Acute exposure to cold air and exercise are considered important inducers of asthma exacerbations.[128,312] Golan et al.[312] examined asthma exacerbation in 147 young adults engaging in HA trekking. In this study 60% of the subjects had an asthma attack, and two independent risk factors for attacks during travel were determined: frequent use (>3 times weekly) of inhaled bronchodilators before travel, and participation in intense physical exertion during treks. When both risk factors were present, the risk for an asthma attack was 5.5-fold. It was concluded that therapy should be intensified to achieve better disease control and uncontrolled patients should be discouraged from participating in intense HA trekking. Patients should consider the use of short-acting $\beta_2$ agonists or antileukotrienes.[313]

Seys and coworkers studied a group of 18 asthmatic adults climbing the Aconcagua mountain (6965 m, Argentina) and concluded that "exposure to environmental conditions at high altitude (hypoxia, exercise, cold) was associated with a moderate loss of asthma control, increased airway obstruction and neutrophilic airway inflammation. The cold temperature is probably the most important contributing factor as 24-hour cold exposure by itself induced similar effects"[314] and protection of the mouth and nose was recommended (e.g., with a scarf) during rest and exercise.[313]

Chronic exposure to HA could have beneficial effects. Droma and coworkers studied 3196 children 13–14-years-old Tibetan highland residents (3658 m above sea level) who participated in written and video questionnaire investigations (ISAAC Phase III program), and the prevalence of asthma, allergic rhinoconjunctivitis, and eczema over the past 12 months was found to be the lowest among the centers that performed ISAAC worldwide.[315] Rijssenbeek-Nouwens and coworkers reviewed the long-term effect of HA as a treatment for asthma for children and concluded that HA has beneficial effects in patients with severe refractory asthma on symptoms, lung function, and oral corticosteroid requirement, irrespective of atopic status. The suggested mechanisms were decreased levels of mite allergens, pollens, fungal spores, and air pollution in the dry air, as well as high exposure to UV light with immunomodulatory and antiinflammatory effects.[316]

## Cystic Fibrosis

We could find only one published study regarding CF children and exercise at HA. Blau and coworkers looked at the effects of an intensive 4-week summer camp at an altitude of 1500 m on 13 CF patients (9–25 years old, mean $FEV_1$ predicted = 75%). The exercise during the camp was mainly done during physiotherapy and by climbing mountains. Full assessment was done at sea level before and after the camp. At sea level, as well as at the camp, rest $SpO_2$ were in the normal range and during intense exercise lowered to 94% at sea level (no training effect) and 89% at 1500 m. There was a significant training effect on $\dot{V}O_2$ and AT. $FEV_1$ did not improve, but minute ventilation and maximal minute ventilation did, and it was concluded that this could be respiratory muscle training effect.[317] CF patients with obstructive airways disease are at significant risk for decreased $SpO_2$ during exercise. Ryujin and coworkers studied 50 CF patients (15–50 years old, mean $FEV_1$ predicted = 54%) and evaluated oxygen saturation during maximal exercise (cycle ergometer ramp test) at moderate altitude (1500 m). Percent predicted $FEV_1$ and $FEV_1/FVC$ ratio most highly correlated with arterial oxyhemoglobin saturation at peak exercise. $\dot{V}O_{2max}$ was measured at 1500 m but comparison to sea level values was not reported.[318]

Lung function in 36 adults with CF (19–47 years old, $FEV_1$ = 66%) at sea level and after 7 hours at HA (2650 m) was assessed before and after mild exercise (5 minutes of cycling at a work load of 30 watt). Pulmonary function test improved significantly from sea level, and mild exercise led to pronounced hypoxemia in almost two-thirds of all patients, without relevant symptoms.[319] Predictive equations for hypoxia in CF patients during exposure to HA are available.[320] CF patients are at increased risk to develop HA pulmonary edema (HAPE) upon fast ascending to HA and exercising.[300]

Few studies have addressed the dilemma of low cabin pressure during air travel in children with chronic lung disease. During commercial air travel the cabin pressure is reduced to that found at an altitude of 1800–2450 m, corresponding to a $P_IO_2$ ~125 mm Hg and $P_AO_2$ ~65 mm Hg.[321] Buchdahl and coworkers evaluated 87 children with CF (7–19 years old), preflight (hypoxic chamber) and during flight, and concluded that preflight spirometry was a better predictor of desaturation during flight than preflight hypoxic challenge.[322] Thews and coworkers investigated 10 moderate CF patients (age 19–35-years-old, $FEV_1$ = 55% predicted) and 27 healthy control subjects in a hypoxic chamber where the ambient pressure was reduced to that found at 2000 and 3000 m and reported that pulmonary function tests ($FEV_1$, FVC) did not change significantly while they slightly improved in the control group. At each ambient pressure the $SpO_2$ in the control subjects was 3%–4% higher than in the CF patients, with $SpO_2$ for all subjects higher than 80% (risk level for complications during commercial flights).[321]

## Bronchopulmonary Dysplasia

One case report was found regarding BPD and exercise at HA. Lovering and coworkers reported a 27-year-old male with a history of BPD ($FEV_1$ = 66.5% predicted, normal FVC and DLCO, $\dot{V}O_{2max}$ = 41.4 mL/kg per minute, 92% predicted) and a case of HAPE.[300] Significant changes in gas exchange were observed at maximal hypoxic exercise (incremental cycle ergometer test while breathing

$F_IO_2 = 0.12$). $\dot{V}O_{2max}$ was reduced ~50% to 21.9 mL/kg per minute and $PaO_2$ decreased from 67.8 mm Hg (normoxic exercise) to 29.9 mm Hg (hypoxic exercise). These findings suggest higher susceptibility of subjects with a history of BPD to hypoxemia[323] and HAPE.[300]

## Exercise and Laryngeal Obstruction

Exercise-induced laryngeal obstruction (E-ILO) is the preferred term based on a recent international multispecialty consensus document, describing the condition in which glottic or supraglottic structures inappropriately obstruct the larynx during exercise, "causing breathing problems."[324] This condition was formerly known under the umbrella terms of *vocal cord dysfunction* and *paradoxical vocal fold motion*, and was first described in the modern literature in 1983.[325] It was recognized as a cause of adolescent exertional dyspnea in 1984 and later famously described as a cause of "choking during athletic activities."[326,327]

E-ILO is important to the pediatric pulmonologist for its combination of prevalence and impact. It is estimated to affect roughly 5% of the adolescent population.[328] Its impact was first characterized in terms of its identification as an entity distinct from asthma. When clinicians made this diagnosis, it became possible to decrease the cost and side effects associated with inappropriate treatment with asthma medication.[329] A second domain of impact is quantified in terms of the symptom burden experienced by patients, as patients with E-ILO are not able to exercise comfortably and may potentially change exercise habits.[330] The impact of E-ILO in terms of perturbations of exercise physiology variables has not been described to date.

Currently, the mechanism of E-ILO is unclear, although many hypotheses exist. The roles of upper airway size, epithelial integrity, tissue pliability, tissue tone, tissue reactivity, neural plasticity, and neurophysiological coupling with the lower airways have been pondered, but are unclear.[331,332] Behavioral traits of affected patients may also contribute in undefined ways.[333,334]

Patients with E-ILO generally present with a chief complaint of exertional dyspnea. Historical clues to the diagnosis may include a description of breathing as noisy, frightening, and distressing to observers. The time course of symptoms is distinct from asthma and localized to short durations that are generally associated with very high WRs. The condition typically does not respond to albuterol.[327] The history can also overlap with the history of the prototypical patient with asthma, in part because the condition can coexist with asthma.

Diagnostic procedures and criteria have not been standardized within or across specialties. In practice and in the literature, a variety of methods have been used to diagnose E-ILO, including documentation of a characteristic history, noninvasive techniques, resting laryngoscopy, postexercise laryngoscopy, preexercise and postexercise laryngoscopy, and continuous laryngoscopy during exercise (CLE).[335–339]

CLE, a procedure in which a flexible laryngoscope is mounted in place during high-intensity exercise challenges, has been advocated as the diagnostic method of choice because glottic and supraglottic behavior varies across rest, incremental exercise, and recovery. It is now clear that, even during periods of maximal symptomatology at peak work capacity, observed maximal laryngeal obstruction is not synonymous with complete inspiratory glottic or supraglottic obstruction (Video 12.1▶). The resolution of laryngeal obstruction during recovery is rapid (starting in <30 seconds), precluding representative assessment by postexercise laryngoscopy (Fig. 12.12).[340]

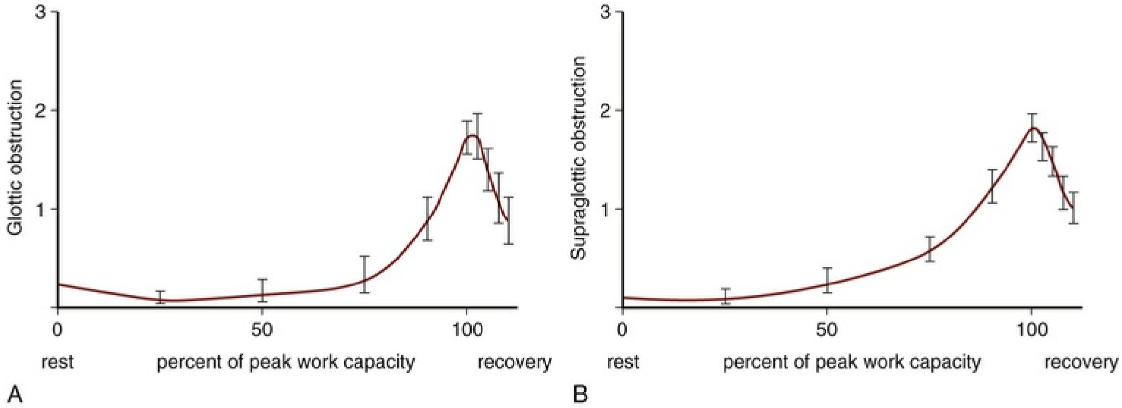

**FIG. 12.12** Laryngeal obstruction across a symptom limited incremental exercise test and recovery period in subjects with moderate/severe inspiratory glottic

adduction observed during continuous exercise laryngoscopy. Plots A and B represent glottic and supraglottic obstruction, respectively. Confidence intervals surround estimates, which were based on Roksund's scoring scale. At submaximal exercise, obstruction at both levels is minimal, at peak exercise is not complete, and rapidly resolves during recovery. (Modified figure reproduced with permission Olin JT, Clary MS, Fan EM, et al. Continuous laryngoscopy quantitates laryngeal behaviour in exercise and recovery. *Eur Respir J* 2016;48:1192-1200.)

There is noted variability in the therapeutic modalities used to treat E-ILO. Therapies that have been promoted include medical intervention (with anticholinergic agents and treatment of associated conditions),[341] surgical interventions (which minimize supraglottic obstruction),[342] and behavioral interventions (including respiratory retraining, voice therapy, biofeedback, hypnosis, and cognitive behavioral therapy).[325,329] Recently, therapeutic laryngoscopy during exercise, an innovative procedure designed to treat E-ILO by harnessing visual laryngeal biofeedback during exercise, was also described (Fig. 12.13).[343] In 2016, high-quality clinical trials designed to evaluate the relative effectiveness of different therapeutic techniques have not been performed.

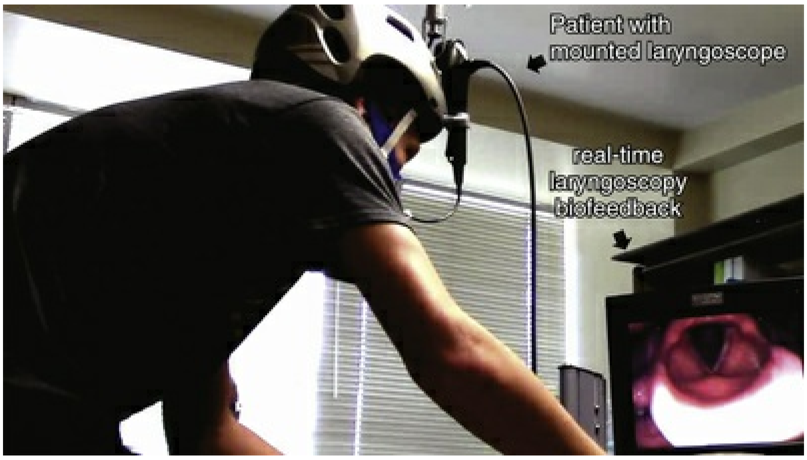

**FIG. 12.13** A 15-year-old male with refractory exercise-induced laryngeal obstruction performs therapeutic laryngoscopy during exercise. (From Olin JT, Deardorff EH, Fan EM, et al. Therapeutic laryngoscopy during exercise: a novel non-surgical therapy for refractory EILO. Pediatr Pulmonol 2017;52(6):813-819.)

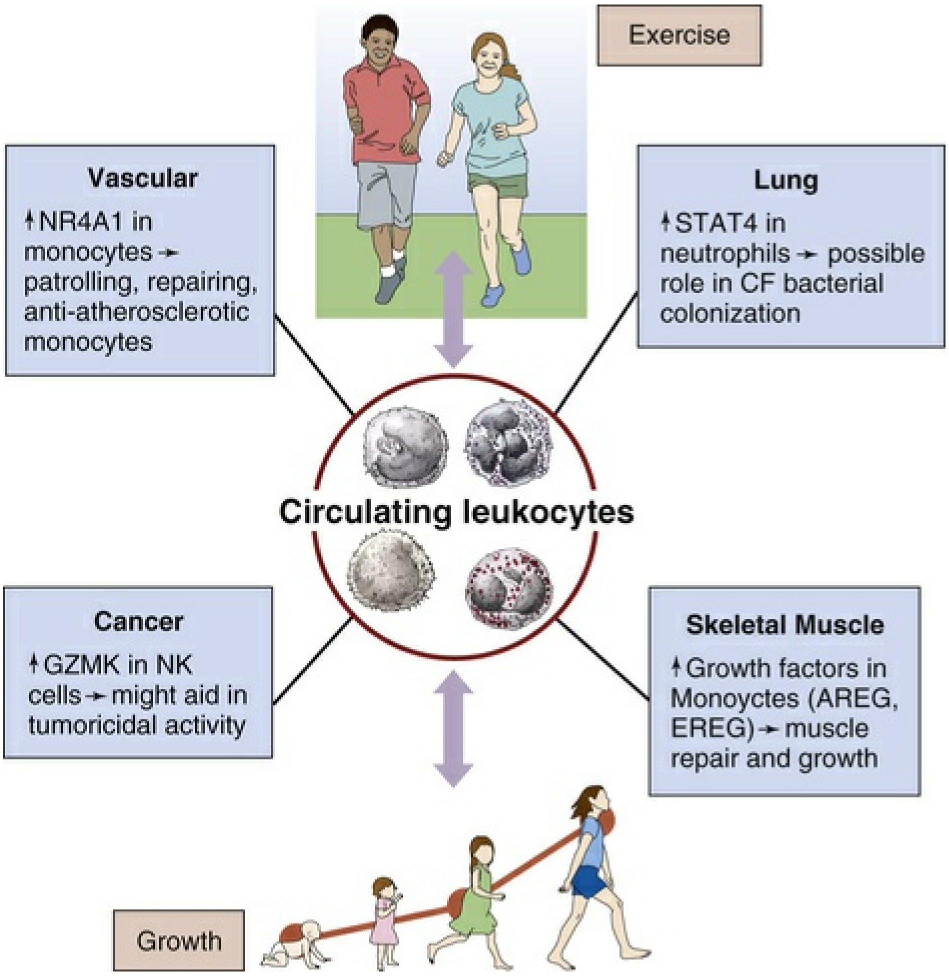
Research into E-ILO is in its infancy, in part due to the lack of field tests and simple diagnostic tests. Notable gaps in the literature include our poor understanding of disease mechanism, disease phenotypes, and the relative effectiveness of various therapeutic modalities. Moving forward, these are critical areas that must be understood to improve care of these patients.

## Toward the Future: Exercise in the Age of Omics

Pediatric pulmonologists are keenly interested in the impact of respiratory disease during childhood on lung health across the lifespan. Developmental biologists, pediatricians, and other child health care specialists have long suspected that exercise during infancy, childhood, and adolescence is not merely play, but is essential for healthy growth and development. The pattern and intensity of PA during key stages of growth and development can provide the organism with mechanical and other thermodynamic inputs, essential information that could optimally adapt the growing child to his or her specific environment. Precisely how the molecular transducers of PA interact with the molecular transducers of normal growth and development remains poorly understood. But recent advances in "omics," namely genomics and epigenetics, metabolomics, and proteomics, now provide exciting approaches and tools that can be used for the first time to address this gap.

Exciting preliminary data and pioneering publications from a variety of investigators are beginning to identify the effect of brief exercise on gene and microRNA expression of these cells (Fig. 12.14). Several specific mechanisms have been identified in child health that link exercise and innate immune cell function with disease prevention and clinical outcomes.[65,344–348] Many of the genomic and epigenetic pathways identified in leukocytes of children and adults are related to growth and repair, and prevention of diseases such as asthma, cancer, and atherosclerosis.[349,350] Advanced use of techniques such as flow cytometry has stimulated research into the effect of acute and chronic exercise on leukocyte function (summarized recently by Gjevestad and coworkers[351]). These studies include the impact of exercise on mitochondrial function[352] and oxidative stress,[353,354] each of which has been implicated as an essential component of the molecular transduction of PA in other tissues such as skeletal muscle.[355–357]



Exercise
Vascular
↑NR4A1 in monocytes → patrolling, repairing, anti-atherosclerotic monocytes
Lung
↑STAT4 in neutrophils → possible role in CF bacterial colonization
Circulating leukocytes
Cancer
↑GZMK in NK cells → might aid in tumoricidal activity
Skeletal Muscle
↑Growth factors in Monoyctes (AREG, EREG) → muscle repair and growth
Growth

**FIG. 12.14** Examples of gene expression changes in circulating leukocytes following brief exercise. These data reveal intriguing mechanistic links between physical activity and health. We hypothesize that these effects are influenced by growth and maturational status. *AREG*, EGF-like growth factor Amphiregulin; *CF,* cystic fibrosis; *EREG*, EGF-like growth factor Epiregulin; *NK*, natural killer. (Data from Radom-Aizik S, Zaldivar Jr. FP, Haddad F, Cooper DM. Impact of brief exercise on circulating monocyte gene and microRNA expression: implications for atherosclerotic vascular disease. *Brain Behav Immun* 2014;39:121-129; Radom-Aizik S, Zaldivar Jr. F, Leu SY, Galassetti

P, Cooper DM. Effects of 30 min of aerobic exercise on gene expression in human neutrophils. *J Appl Physiol* 2008;104:236-243; and Radom-Aizik S, Zaldivar FP, Haddad F, Cooper DM. Impact of brief exercise on peripheral blood NK cell gene and microRNA expression in young adults. *J Appl Physiol* 2013;114:628-636.)

The sequencing of the human genome (completed in 2003 by the Human Genome Project) launched a new era of discovery in human biology. Technologies such as microarrays and sequencing permitted investigators to interrogate the expression of the whole human genome and to identify specific genes, or interacting pathways of genes, that could play a role in health and disease. More recently, these techniques have been used to explore an intriguing aspect of transcription mechanisms, namely the timing of gene expression across the lifespan.[358]

Epidemiological studies suggest that the early-life environment can affect epigenetic regulation of specific genes and make an important contribution to disease risk factors later in life. For example, exposure to famine in utero is associated with altered methylation status of genes related to the cardio-metabolic disease (CMD) phenotype in elderly individuals. Furthermore, methylation of the retinoid-x-receptor-a in umbilical cord predicted greater than 25% of the variation in age- and sex-adjusted fat mass in children at 6 and 9 years old. Such findings imply that epigenetic changes that are induced by environmental exposures early in life can persist beyond the period of challenge. Alisch and coworkers investigated pediatric age-associated DNA methylation changes in peripheral blood mononuclear cells (PBMCs) of 398 healthy males (3–17 years old) and reported 2078 loci that exhibit age-associated DNA methylation differences.[359]

Human beings no longer live in the ecological niche into which they evolved. Survival for our hunter-gatherer human ancestors depended on a remarkably efficient integration of neuromotor, cardiovascular, and respiratory systems. Being “fit” meant the capability to quickly escape predation and the ability to expend just enough energy to access food while remaining in net-positive energy balance. Modern, more sedentary humans are facing the ominous fact that absent repeated bouts of exercise (each a sizeable physiological challenge to cellular homeostasis), fitness dissipates and the risk of serious disease is increased. Exercise activates a complex set of mechanisms that can affect a panoply of tissues ranging from mitochondria to bone. The molecular transducers of exercise in large measure prepare the organism to better deal with the thermodynamic, oxidative, and inflammatory stress of physical work.

The immediate implications and long-term consequences of insufficient PA are particularly concerning for child health. Childhood is a "critical period of growth and development" in which environmentally modifiable mechanisms (likely involving epigenetic reprogramming), can shape health across the lifespan. In the context of child health, the information gained from omics mapping of exercise responses can transform health policy that promotes optimal exercise in communities, schools, and in individual families, and begin to mitigate the current epidemic of childhood obesity. This approach will also impact an equally challenging and looming health problem—namely the role of exercise in children with chronic disease and disability. As medicine has advanced in recent years, there is an increasingly large population of child survivors of previously often fatal diseases and conditions (e.g., prematurity, CF, sickle cell anemia, childhood malignancies, and congenital heart disease). These conditions inevitably limit the child's ability to engage in exercise, and a better biologic definition of "healthy" exercise will pave the way for more precise and effective exercise prescriptions for the child or adolescent with chronic disease and disability.

## 13

# Integrating Patient-Reported Outcomes Into Research and Clinical Practice

*Alexandra L. Quittner PhD, Christina J. Nicolais MS, Estefany Saez-Flores MS*

Patient-centered care is based on a collaborative relationship between the patient and health care professional, in which the patient's perceptions, beliefs, and preferences are taken into account.[1,2] This provides an opportunity to develop a culture of collaboration in which patients can be actively engaged in decision-making.[3] One effective, standardized method of including the patient and family perspective on both clinical care and daily functioning is the use of patient-reported outcomes (PROs).[4] PROs are developed using patient input and are designed to systematically measure the frequency and impact of the disease on daily functioning, thus capturing the patient's "voice." In 2009, the US Food and Drug Administration (FDA) recognized the importance of PROs for evaluating the efficacy of new medications and laid out a framework for PRO development.[5,6] This guidance reflects a profound change in the process of regulatory approval of new medications and outcomes research.[7] This chapter focuses on the reliability, validity, and utility of PROs for children with respiratory diseases in the context of both research and clinical practice.

## Definition of a Patient-Reported Outcome

A PRO is any measure of a patient's health status that reflects how he/she functions, feels, or survives, as reported by the patient him/herself.[3] Health-related quality of life (HRQoL) measures are one type of PRO that include “profiles” of functioning across several domains (e.g., respiratory symptoms, physical functioning, treatment burden).[4,5] These instruments measure aspects of functioning that are known only to the patient, including his/her symptoms, behaviors, and daily functioning. PROs can be used for several purposes: (1) as primary or secondary outcomes in clinical trials of new medications and treatments (including behavioral interventions), (2) to characterize the course of the disease and its progression, (3) to assess the effects of a disease on multiple aspects of patient functioning, and (4) to develop individualized treatment plans.[8–11]

To date, 27% of registered clinical trials include a PRO as either a primary or secondary endpoint.[12] This has nearly doubled from 14% in 2009[13] and is expected to increase as new PROs are developed.[14,15] This trend has been attributed to the movement toward collaborative care, as well as the complexities and burdens of treating and managing chronic conditions. In the period from 2006 to 2010, 17% of new drugs approved by the FDA used a PRO as a primary endpoint.[16] In 2009, Aztreonam for Inhalation was approved on the basis of a PRO (Cystic Fibrosis Questionnaire-Revised Respiratory [CFQ-R] Symptom Scale).[17] This was the first time a respiratory drug was approved using a PRO as the primary endpoint, highlighting the importance of the patient's perspective.[18]

## Development and Utilization of Patient-Reported Outcomes

To utilize a PRO in a drug registration trial, it must be developed using patient and stakeholder input and meet strict psychometric criteria (e.g., reliability, validity, responsivity). A conceptual framework links the relevant concepts identified by qualitative data to the label claim (e.g., improvement in respiratory symptoms). This claim must also be hypothesized and tested, followed by calculation of several types of reliability and validity (Table 13.1). PROs must be sensitive to change on both an individual and group level.

## Table 13.1

## Psychometric Criteria for a Patient-Reported Outcome

| Measurement Property | Definition |
|---|---|
| **CONSTRUCT VALIDITY** | |
| ▪ Content or face validity | ▪ Extent to which items and response options are relevant and measure the domain |
| ▪ Convergent validity | ▪ PRO correlates with health-related variables in expected directions and with related measures |
| ▪ Divergent validity | ▪ Scores on disparate measures are not correlated (e.g., digestive symptoms and lung function) |
| ▪ Discriminant validity | ▪ Instrument distinguishes between groups sharing common characteristics (e.g., healthy vs. unhealthy) |
| ▪ Responsivity | ▪ Ability of PRO to detect change in predicted direction or no change when patient is stable |
| **INTERPRETABILITY** | |
| ▪ MCID or the MID | ▪ Smallest difference that can be reliably detected by patients and has clinical meaning |
| **RELIABILITY** | |
| ▪ Internal consistency | ▪ Whether items in a domain are intercorrelated, as evidenced by an internal consistency statistic (e.g., coefficient $\alpha$) |
| ▪ Interrater reliability | ▪ Agreement between child and parent proxy on the construct or rating choices |
| ▪ Test-retest | ▪ Stability of patient report over time when no change has occurred in the measured concept |

*MCID,* Minimal clinically important difference; *MID,* minimal important difference; *PRO,* patient-reported outcome.

Proceedings of the American Thoracic Society is an official journal of the American Thoracic Society.

To interpret the magnitude of this change, several qualitative and statistical methods have been developed. The minimal important difference (MID) score establishes the smallest, clinically meaningful, change that a patient can reliably detect.[19–21] The MID can be established using a visual analog scale, which asks the patient to indicate the amount of change he/she has experienced (i.e., anchor-based method). The MID can also be determined using statistical methods, such as calculation of ½ standard deviation (SD) of change or 1 standard error of measurement. These analyses are bolstered by triangulating these values to establish the MID for a particular scale. A new term, the *clinically important difference* (CID), can also be used to identify clinically relevant changes in scores between two treatment groups.[22] This should be followed by a response distribution curve mapping individual changes for the two groups; ideally, there should be maximal separation between these curves.

## Health-Related Quality of Life Measures

HRQoL measures are one of the most frequently used types of PROs first characterized by the World Health Organization's 1946 definition of health, which was “a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity.”[23] HRQoL measures are multidimensional, profile instruments focusing on several aspects of daily functioning. Typically, HRQoL measures evaluate four core domains: (1) disease state and physical symptoms, (2) functional status (e.g., performing daily activities), (3) psychological and emotional functioning, and (4) social functioning. Patient's scores are likely to differ across different domains of functioning and, thus, a total score should not be calculated. HRQoL instruments can track the natural progression of a disease, evaluate responsivity to pharmacological or behavioral interventions, and facilitate shared medical decision-making. For example, if a patient starts a new treatment for asthma, an HRQoL measure can assess its effectiveness in reducing asthma symptoms, such as wheezing. The tool can also be used to evaluate whether this new treatment is burdensome if this domain is measured.[4,24]

HRQoL instruments can be either generic or disease-specific.

Generic measures are composed of general items that are relevant to populations with and without a chronic illness. Examples include the Pediatric Quality of Life Inventory,[25] the Child Health and Illness Profile,[26] and the Youth Quality of Life Instrument.[27] Generic HRQoL measures can be utilized across patient populations to compare the impact of a disease on different patient groups or to perform cost utility analyses (e.g., EuroQol-Five Dimensions Questionnaire [EQ-5D]).[28] However, these measures are not specific to the symptoms experienced by patients with a particular illness; therefore, they are less sensitive to their effects on daily functioning and are not acceptable to test the efficacy of new medications.[29]

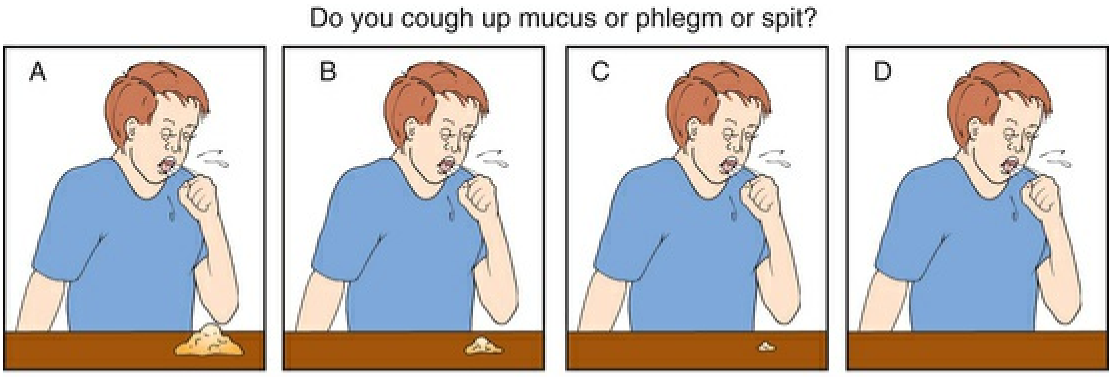
In contrast, disease-specific instruments are designed to assess the unique symptoms and challenges of a particular patient population. For example, a hallmark symptom of cystic fibrosis (CF) is excess mucus production. This symptom would not appear on a generic measure or one focused on a different respiratory condition, such as asthma. Thus, inclusion of items that are most relevant to a specific condition leads to greater sensitivity to treatment effects and is more informative for clinical care. This is the rationale for using disease-specific instruments for the purposes of drug registration trials.[30]

## Developmental Considerations

Developing HRQoL measures for children poses unique challenges, ranging from differences in reading ability to the shifting importance of peers, school, and parents over the course of development. Comprehension and the ability to respond to items require several cognitive skills, such as focused attention, receptive and expressive language, and a conceptual understanding of the illness. All of these skills emerge gradually and at different points across development. Furthermore, the relevance and importance of a given domain is likely to change over the course of childhood and adolescence.[4] For example, social functioning is integral to adolescents' overall quality of life but is less relevant for preschoolers. Thus measures created within a developmental age group are more valid than measures downwardly extended from adult instruments. This ensures that the most relevant areas of functioning are measured in a developmentally appropriate way for a particular age group.[31]

HRQoL measures for children must undergo rigorous testing to ensure that individuals in the target age understand the vocabulary and concepts contained in the questionnaire. Research shows that children between 2 and 6 years have a more limited understanding of medical terms and concepts.[32] Children in this age group are able to report on observable areas of health, such as symptoms and levels of pain, using a pictorial format. They may, however, have more difficulty reporting on their emotional and social functioning.[33] By school age, children demonstrate a better understanding of the interplay between their health status and daily functioning. In fact, several studies have found that school-age children are able to provide reliable reports of their symptoms and functioning.[31–33]

Changes in cognitive and attentional capacity across development underscore the importance of response options and mode of administration when eliciting information from children. PROs can be administered electronically (computer, tablet), accompanied by colorful, animated pictures to increase understanding and attention.[9,15,34] Alternatively, to reduce errors based on reading difficulties and distractibility, measures can be administered to young children by an interviewer. For preschoolers, the CFQ-R Preschool version is administered by an interviewer using pictures to represent the items and rating scale options. In addition, because young children tend to select response options at endpoints rather than using the full range of responses, a forced choice format is a useful alternative. Research shows that children as young as 3 years old can make forced choices. To make it more interactional and rewarding, we also use concrete rewards, such as stickers, to maintain their focus (Fig. 13.1).



Do you cough up mucus or phlegm or spit?
A
B
C
D

**FIG. 13.1** (A–D) Example of CFQ-R response choices for the preschool version. The interviewer asks "Do you cough up mucus or phlegm or spit?" Children are asked to first choose between the extreme choices (1 and 4) and then to discriminate between the extreme and less extreme choice (e.g., 1 and 2, "Do you think you cough up very, very much phlegm, or a bit of phlegm?").

## Use of Proxy-Respondents

Parents or other caregivers can also complete HRQoL measures for young children to provide a different perspective.[35] Parent reports tend to correlate better with child reports for observable phenomena, such as physical functioning and symptom frequency (e.g., climbing stairs, coughing), but more poorly for emotional and social functioning (e.g., sadness).[36] Findings have suggested that children endorse more emotional distress, somatic complaints, and physical difficulties than their parents.[37] Thus, proxy measures cannot typically be substituted for patient reports. However, proxy respondents may be particularly useful for infants, patients with severe disease, or those with significant cognitive limitations.[38] In addition, differences between respondents may inform the focus of a clinic visit, medical decision-making, and health care utilization. Although proxy measures for health care providers have been developed, their validity is limited, because providers spend less time with their patients and observe them across fewer contexts.

## Clinical Utility

Use of HRQoL measures in routine practice facilitates systematic, efficient collection of information about patients' ratings of their daily functioning. These data serve several purposes: (1) promoting communication between the patient and provider, (2) identifying frequently overlooked problems (e.g., school functioning), (3) monitoring disease progression and treatment burden, and (4) tailoring interventions to key aspects of a patient's daily life.[4,39] Thus both quality of life and health outcomes may improve as a result of integrating information from these instruments into routine care. Enhanced communication and monitoring symptoms are the best established benefits of this integration.[40,41]

First, HRQoL measures can provide a systematic way to facilitate discussions between patients and providers. Depending on the patient, he/she may report some symptoms (i.e., frequent cough), but disclose others only when directly asked (e.g., fatigue or absences from school or work).[42] Research shows that both patients and physicians find these assessments helpful in identifying patient concerns, which has important implications for health outcomes.[41] Numerous studies have found that discussions of both physical and psychosocial issues during medical visits lead to improved treatment adherence, higher patient satisfaction, and fewer symptoms.[43,44]

A second benefit is the identification of frequently overlooked symptoms and problems that are important to the patient (e.g., depression, treatment burden).[45,46] This is particularly critical in the management of chronic respiratory diseases, because multiple domains of functioning are affected typically and treatment regimens are both time- and energy-intensive.[47–49] For example, patients with CF may spend 2 to 4 hours each day completing prescribed treatments, leading to social isolation and depression.[45,49] In addition, physiological measures, such as lung function and nutritional status, correlate modestly with HRQoL measures that assess symptom frequency, physical functioning, daily activities, or emotional functioning.[17,50] Thus, HRQoL data may alert providers to these critical issues, which are not captured by traditional medical assessments. Note that most of this research has been conducted with adults, highlighting a need for research in pediatric populations.

When given at regular intervals, HRQoL measures can monitor disease course, both in terms of natural progression and response to drug or behavioral interventions. Monitoring disease progression can lead to early identification of new concerns (e.g., weight loss) or ongoing challenges (e.g., increased fatigue). In addition, HRQoL assessment can measure the patient's responsivity to a new treatment. Because these instruments are multidimensional, they allow for differentiation of the benefits of a new medication (e.g., improvement in respiratory symptoms) from its side effects (e.g., increased treatment burden).[40] It is also possible that patients with the same lung function score may report very different levels of functioning in physical, social, or emotional domains.

HRQoL feedback can be used by providers to inform their treatment decisions and ensure that they are patient-centered, considering the individual's perceptions of their treatments, how they affect daily functioning, and their priorities.[40] HRQoL feedback has been shown to impact clinical decision-making in CF patients listed for lung transplant,[51] arthritis, epilepsy, and cancer.[52] Furthermore, if data are collected systematically on HRQoL instruments and included in national and international registries, trends identified in these data can be used to (1) predict health outcomes for individuals (e.g., lung function decline, number of exacerbations), (2) predict an individual's response to a new treatment, (3) conduct comparative effectiveness studies of similar medications (e.g., inhaled antibiotics), and (4) identify which treatments are most likely to maximize benefits and minimize costs.[53]

Studies testing the feasibility of integrating HRQoL and physiologic measures in routine care for respiratory disorders are just beginning but demonstrate considerable promise.[54,55] For example, adult patients with CF are using home spirometers that are linked to their pulmonary center along with daily symptom diaries.[54] Utilizing HRQoL and medical measures together may allow the CF team to identify early signs of an exacerbation, prompting a prescription for antibiotics or a visit to the clinic. A study by Santana and colleagues demonstrated that administration of HRQoL measures was feasible in a lung transplant clinic and did not prolong clinic visits.[56] Results also demonstrated improved communication between patients and health care providers and better patient management (e.g., medication changes). Furthermore, preliminary findings in pediatric and adult asthma clinics indicated that patients and providers were satisfied with implementation of an electronic quality of life (e-QOL) questionnaire about asthma during their routine visits.[57] The feasibility of routine assessment of quality of life is improving given technological advances (e.g., web- and computer-based applications) that increase the efficiency of measure completion and scoring.[39,58,59]

# Summary

In summary, as the medical community transitions toward a patient-centered model of care, PROs will become a central mechanism for improving patient-provider communication, measuring health outcomes in chronic respiratory conditions, obtaining regulatory approval for new medications, and informing clinical decision-making. To move the field forward, we need to develop and utilize HRQoL instruments that are disease-specific and demonstrate good psychometric properties (e.g., reliability, validity). The following section reviews the strengths and limitations of disease-specific HRQoL measures for several pediatric respiratory disorders (i.e., aerodigestive disorders, asthma, bronchopulmonary dysplasia, CF, primary ciliary dyskinesia, and sleep apnea). Based on this information, we have recommended the best instrument for each condition.

# Review of Disease-Specific Respiratory Health-Related Quality of Life Measures

## Aerodigestive Disorders

### Vocal Cord Dysfunction

To date, four HRQoL measures for vocal cord dysfunction have been developed for pediatric populations. Three of these measures are completed by parents, and one offers both parent and child versions. All of them are brief with minimal respondent burden (Table 13.2). Additionally, these instruments demonstrate good test-retest reliability and discriminant and convergent validity. However, internal consistency for the pVHI has not been reported. Most of these measures are limited by their reliance on parents or caregivers as informants and thus, they do not capture the patient perspective. The pediatric voice symptom questionnaire (PVSQ) has both child and parent proxy versions, and the child version utilizes pictorial responses, which enables patients who have different verbal abilities to complete the measure. Unfortunately, none of the instruments have established MIDs, and additional research on responsiveness is needed. Finally, the pediatric voice outcome survey (PVOS) lacks good psychometric properties and consists of only four items, which provides little information across domains.

## Table 13.2

### Health-Related Quality of Life for Children With Aerodigestive Disorders

| Measure | Number of Items and Domains | Age Range and Respondent | Psychometrics: Reliability | Psychometrics: Validity |
|---|---|---|---|---|
| **AERODIGESTIVE DISORDERS** | | | | |
| pVHI[60–62] | Number of items = 23<br>Domains (3): Functional, physical, emotional<br>Total and visual analog scale | 4–21 years<br>Parent only | Test–Retest = .77–.95<br>*No internal consistency reported* | ▪ Discriminates between healthy children and those prelaryngotracheal or postlaryngotracheal reconstruction<br>▪ Discriminates between children with benign vocal cord pathologies and other airway conditions |
| PVOS[63,64] | Number of items = 4 | 2–18 years<br>Parent only | $\alpha$ = .69–.86 by age<br>Test-retest = .89 | ▪ Discriminates between patients with and without tracheotomies ($P$ = .004)<br>▪ Discriminates between patients before and after adenoidectomy<br>▪ Does not discriminate |

| | | | | |
|---|---|---|---|---|
| | | | | between healthy children and those with paradoxical vocal fold dysfunction |
| PVR-QOL[65] | Number of items = 10<br>Domains (2): Social-emotional, physical-functional | 2–18 years<br>Parent only | $\alpha = .96$<br>Test-retest = .80 | ▪ Correlates with the PVOS (r = .70)<br>▪ Responsive to change in 9 patients with adenoidectomy ($P < .001$)<br>▪ Discriminates between healthy children and those with vocal fold paralysis, vocal nodules, or paradoxical vocal fold dysfunction |
| [a]PVSQ[66] | Number of items = 19 | 5–13 years<br>Child & parent versions<br>Child version includes pictorial answer choices | $\alpha = .88$ (child) $\alpha = .82$ (parent)<br>Test-Retest = .88 (child)<br>Test-Retest = .76 (parent) | ▪ Discriminates between healthy children and those with dysphonia |
| [a]FS-IS[67] | Number of items = 18<br>Domains (3): Daily activities, worry, feeding difficulties | Parents/caregivers of children with feeding/swallowing disorders | Total score $\alpha = .89$; daily activities $\alpha = .88$, worries $\alpha = .85$, feeding difficulties $\alpha = .85$ | ▪ Three subscales and total score correlated with PedsQL Family Impact Module<br>▪ Discriminates between children with and without a feeding tube on completion of daily activities |
| [a]VELO[68–70] | Number of items = 23 (patient), 26 (parent)<br>Domains (6): Speech limitation, swallowing, situational difficulty, emotional impact, perception by others, caregiver impact | 5–17 years<br>Patient- and parent-report | Parent $\alpha = .96$, Patient $\alpha = .95$ all domains $\alpha > .70$ Test-retest: Parent ICC > .6 for total score and domains | ▪ Factor analysis yields four-factor solution with some domains loading onto the same factor<br>▪ Parent- and patient-report significantly correlated with the PedsQL4.0 (r = .73)<br>▪ Discriminates between patients with and without velopharyngeal insufficiency<br>▪ Responsive to treatment<br>▪ Established MCID |

[a]Denotes the recommended measures.

*FS-IS,* Feeding/swallowing impact survey; *ICC,* intraclass correlation coefficient; *MCID,* minimal clinically important difference; *pVHI,* pediatric voice handicap index; *PVOS,* pediatric voice outcome survey; *PVR-QOL,* pediatric voice-related quality of life; *PVSQ,* pediatric voice symptom questionnaire; *VELO,* VPI effects on life outcomes instrument.

Adapted with permission from Quittner AL, Modi A, Cruz I. Systematic review of health-related quality of life measures for children with respiratory conditions. *Paediatr Respir Rev.* 2008;9(3):220–232.

### Recommendation.

Based on these findings, we recommend the PVSQ, because it has child and parent versions with age-appropriate pictorial responses and strong psychometric properties.

## Feeding/Swallowing and Velopharyngeal Insufficiency

Currently Feeding/Swallowing Disorders and Velopharyngeal Insufficiency each have only one PRO measure. The VPI effects on life outcomes (VELO) includes both patient and parent versions, strong internal consistency, and good construct, convergent, and discriminant validity. The VELO has good test-retest reliability for the parent version, but this has not been evaluated for the child version.

The Feeding/swallowing impact survey (FS-IS) is the only published PRO for feeding/swallowing disorders. It is brief, has good internal consistency for the domain and total scores, and demonstrates good construct and discriminant validity. No child-report version of the measure is currently available.

### Recommendation.

Based on their strong psychometric properties, both the VELO and the FS-IS are recommended for use with their respective populations. However, the FS-IS has no MID, and a child report version is needed.

# Asthma

There are currently 13 disease-specific HRQoL measures for children with asthma. While most of these measures demonstrate good internal consistency and test-retest reliability, they vary in their clinical utility and responsiveness to change (Table 13.3). Specifically, only the pediatric asthma quality of life questionnaire (PAQLQ) has an established MID, enhancing its clinical utility in assessing meaningful change to pharmacological or behavioral interventions. These measures vary with respect to informant type, age range, and practical utility (e.g., language translations, respondent burden). While several measures have corresponding child and parent versions, few include self-report versions for children under 5. Translations into multiple languages exist for three measures (childhood asthma questionnaires [CAQ], DISABKIDS-Asthma Module, and PAQLQ).

## Table 13.3

## Health-Related Quality of Life Measures for Children With Asthma

| Measure | Number of Items and Domains | Age Range and Respondent | Psychometrics: Reliability | Psychometrics: Validity |
|---|---|---|---|---|
| **ASTHMA** | | | | |
| AMA[71] | Number of items = 55<br>Domains: Total score only | 6–12 years<br>Child<br>No parent version | α = .93<br>Test-retest = .57 | ▪ Moderately correlates with the PAQLQ<br>▪ Responsive to a week-long asthma day camp |
| AAQOL[72,73] | Number of items = 32<br>Domains (6): Symptoms, medication, physical activities, emotion, social interaction, and positive effects | 12–17 years<br>Child<br>No parent version | α = .70–.93<br>Test-retest = .76–.90 | ▪ High correlation with PAQLQ (r = .81)<br>▪ Weak to moderate correlation with patient-rated symptom severity, number of hospitalizations, severity of coughing, and severity of wheezing (r's = .25–.65) |
| ARQOLS[74] | Number of items = 35<br>Domains (5): Restriction of social life, | 6–13 years<br>Child<br>No parent version | α = .81–.96 | ▪ Responsive to pharmacological intervention |

The majority of asthma measures have at least one limitation in terms of reliability, validity, sensitivity, responsivity, or clinical utility. With the exception of the PAQLQ, all measures lack an established MID, leaving clinicians and researchers with little guidance on how to interpret what changes in these scores mean. Respondent burden is a limitation of several measures (AMA [About My Asthma], TACQOL-Asthma [TNO-AZL Questionnaires for Children’s Health-Related Quality of Life for Asthma], and LAQ [Life Activities Questionnaire for Childhood Asthma]). Thus, because of the time they take to complete, they are less feasible for use in routine care. In addition, the AMA only provides a total score, which limits providers' ability to isolate problem areas. Furthermore, for those measures with child and parent proxy versions, cross-informant agreement is rarely reported. Finally, additional self-report measures are needed for children under age 5.

### Recommendation.

To date, the PAQLQ is the most widely used asthma instrument. Several studies have demonstrated the PAQLQ's reliability and validity, and it is the only disease-specific asthma measure that has an established MID. The PAQLQ is responsive to both pharmacological and behavioral interventions, and has been translated into over 30 languages. The corresponding parent-proxy measure (Pediatric Asthma Caregiver's Quality of Life Questionnaire) and the computerized/web-based administration options add to the utility of this instrument. The miniPAQLQ, a validated version of the questionnaire with 13 items instead of 23, and a pictorial version for children ages 5 to 7 are also available.

## Cystic Fibrosis

Five measures are available to assess HRQoL in children and adolescents with CF (Table 13.4). All of these are profile measures that assess respiratory symptoms and other domains of functioning. Only the Questions on Life Satisfaction–Cystic Fibrosis (FLZM-CF) and Cystic Fibrosis Questionnaire–Revised (CFQ-R) measure digestive symptoms and a new version of the CFQ-R includes Sinus Symptoms. Although all measures demonstrate good reliability, validity has only been established for the FLZM-CF, CFQol, and CFQ-R. Responsiveness to pharmacological and/or behavioral interventions has been established for most measures, and they all discriminate between levels of disease severity and stable versus exacerbation events. The CFQ-R has been translated into 36 languages and is the only instrument with child and parent proxy versions.

---

**Table 13.4**

## Health-Related Quality of Life Measures for Children With Cystic Fibrosis

| Measure | Number of Items and Domains | Age Range and Respondent | Psychometrics: Reliability | Psychometrics: Validity |
|---|---|---|---|---|
| **Cystic Fibrosis** | | | | |
| CFRSD[91,92] | Number of items = 16<br>Domains (3): Respiratory symptoms, emotional impact, activity impact | 12+Child<br>No parent version | α =.72–.87<br>Test-retest = .71–.91 | ▪ Differentiates between ill and well states<br>▪ Responsiveness is currently being evaluated as part of several clinical trials |
| CFQoL[93] | Number of items = 52<br>Domains (9): Physical, social, treatment issues, chest symptoms, emotional responses, concerns for future, interpersonal relationships, body image, and career | 14 through adulthood<br>No parent version | α = .72–.92<br>Test-retest > .80; .74 for treatment issues | ▪ Discriminates between levels of disease severity<br>▪ Sensitivity to change following intravenous antibiotics, as measured by $FEV_1$ and BMI<br>▪ Correlates with total Short-Form Health Survey (SF-36) scores (r's = .64–.74) |
| [a]CFQ-R[94–96] | Child Version—<br>Number of items = 35<br>Domains (8): Physical, emotional state, social, body image, eating, treatment burden, respiratory, and digestion<br>Adolescent/Adult Version<br>Number of items = 50<br>Domains (12): Physical, emotional state, social, body image, eating, treatment burden, respiratory, digestion, role, vitality, health perceptions, and weight<br>Parent Version—<br>Number of items = 44<br>Domains (11): Physical, emotional state, body image, eating, treatment | 6–13 Child<br>14 through adulthood Adolescent<br>6–13 Parent<br>*Pictorial version for children 3–6 in development* | α = .34–.73 (child);<br>.55–.94 (adolescent);<br>.58–.90 (parent)<br>Test-retest =.45–.90 (teen/adult)<br>Parent-child agreement = .27–.57 | ▪ Teen/adult version correlates with SF-36<br>▪ Child version correlates with PedsQL<br>▪ Discriminates between healthy children and children with CF<br>▪ Discriminates between levels of disease severity<br>▪ Correlates with $FEV_1$, BMI, height, and weight<br>▪ Establishes 4-point MID on Respiratory Scale<br>▪ Sensitivity to change following treatment with IV antibiotics |

| | | | | |
|---|---|---|---|---|
| | burden, respiratory, digestion, vitality, school, and weight | | | ▪ Used in many Phase III clinical trials as a primary endpoint<br>▪ Used as primary endpoint for approval of a new antibiotic |
| DISABKIDS—Cystic Fibrosis Module[97] | Number of items = 37<br>Generic domains (6): Medication, emotion, social inclusion, social exclusion, limitation, and treatment<br>Number of items = 10<br>CF-specific domains (2): Impact (consists of limitations and symptoms), treatment | "Smileys" version for children ages 4–7<br>Child<br>8–16 Child | α =.80–.85<br>*No test-retest reliability reported* | ▪ Distinguishes between clinician-rated illness severity |
| FLZM-CF[98] | Number of items = 9<br>Domains (9): Breathing difficulties/coughing, abdominal pain/digestive trouble, eating, sleep, routine therapy, adherence to daily therapy, significance for others, understanding, and free from disadvantage | 12–17<br>Child<br>16 through adulthood<br>Adolescent<br>No parent version | α = .80<br>Test-retest = .69 | ▪ Child version correlates with KIDSCREEN<br>▪ Discriminates between healthy children and children with CF<br>▪ Adolescent/adult version correlates with $FEV_1$ and amount of time spent doing treatments<br>▪ Discriminates between mild, moderate, and severe disease severity<br>▪ Responsive to change after inpatient rehabilitation and following pulmonary exacerbations |

[a]Denotes the recommended measure.

*BMI,* Body mass index; *CFQoL,* cystic fibrosis quality of life questionnaire; *CFQ-R,* cystic fibrosis questionnaire—revised; *CFRSD,* CF respiratory symptom diary; *$FEV_1$*, forced expiratory volume in one second; *FLZM-CF,* questions on life satisfaction—cystic fibrosis, *MID,* minimal important difference.

Adapted with permission from Quittner AL, Modi A, Cruz I. Systematic review of health-related quality of life measures for children with respiratory conditions. *Paediatr Respir Rev.* 2008;9(3):220–232.

Despite good reliability and validity, some weaknesses were noted. The FLZM-CF only has 1 item per scale, limiting its ability to reflect more complex constructs (e.g., treatment adherence). Additionally, this measure has a 4-week recall period, which is quite long and may increase error.[99] The cystic fibrosis respiratory symptom diary (CFRSD) focuses on respiratory symptoms that are relevant to pulmonary exacerbations rather than using a multidimensional framework. Additionally, an MID value has only been established for the CFQ-R, thus increasing its clinical utility compared to other measures. The CFQ-R has been downwardly extended to children ages 3 to 6 years using pictures with an accompanying parent proxy version (see Fig. 13.1).[14] The CFQ-R Parent Preschool Proxy measure for children under 6 years of age has also demonstrated good construct validity and internal consistency. In contrast, the CFQol, FLZM-CF, and CFRSD measures do not extend below the age of 12.

### Recommendation.

The CFQ-R is the most widely used, well-established, instrument for CF and is recommended for both clinical and research purposes.[17] The CFQ-R covers the widest age range (ages 3 through adulthood). Advantages of the CFQ-R include its availability in more than 36 languages, an established MID of four points for the Respiratory Symptom scale, with an e-PRO version and computerized administration and scoring. Furthermore, CFQ-R scores have been found to correlate with health outcomes, including forced expiratory volume in one second ($FEV_1$)% predicted, body mass index (BMI) percentile, frequency of exacerbations, and improvements following lung transplantation. Sensitivity to change has been established for the CFQ-R in several clinical trials.[100–102] In fact, the Respiratory Symptom scale was used as a primary endpoint in the drug registration trial for aztreonam lysine for inhalation (AZLI).[18]

## Sleep-Related Breathing Disorders

Two measures are available to assess HRQoL in children with sleep-related breathing disorders (Table 13.5). Both instruments rely on parent-proxy reports of sleep disturbances, physical symptoms, and emotional functioning. These instruments extend down to children as young as 6 months and demonstrate adequate psychometric properties. Although both measures can detect postsurgical change, only the obstructive sleep apnea-18 (OSA-18) has an established MID. Despite these strengths, limitations exist with respect to utility and informant type. The OSA-18 uses a 1-month recall period, increasing the potential for recall bias and error. Furthermore, the obstructive sleep disorders-6 (OSD-6) utilizes only one item per scale, which limits its ability to assess more complex constructs. Finally, both measures rely solely on parent or caregiver report, highlighting the need to develop patient-report instruments.

## Table 13.5

## Health-Related Quality of Life Measures for Children With Sleep-Related Breathing Disorders

| Measure | Number of Items and Domains | Age Range and Respondent | Psychometrics: Reliability | Psychometrics: Validity |
|---|---|---|---|---|
| **SLEEP-RELATED BREATHING DISORDERS** | | | | |
| [a]OSA-18[103] | Number of items-18<br>Domains (5): Sleep disturbance, physical symptoms, emotional distress, daytime functioning, and caregiver concerns | 6 months–12 years<br>Parent Only | Item-total correlations = .38–.86<br>Test-retest > .70<br>*No internal consistency reported* | ▪ Discriminates between mild, moderate, and severe sleep apnea<br>▪ Correlates with the OSD-6 and with Brouillette score<br>▪ Correlates with the number of hourly apneic episodes, the number of hypopneic events, adenoid size<br>▪ Responsive to change after surgery<br>▪ Established MID |
| OSD-6[104] | Number of items=6<br>Domains (6): Physical suffering, sleep disturbance, speech and swallowing difficulties, emotional distress, activity limitation, and level of concern | 6 months–12 years<br>Parent only | $\alpha = .80$ across items<br>Test-retest = .69–.86 | ▪ Responsive to change after adenotonsillectomy<br>▪ Correlates moderately with physician estimates of child's QOL<br>▪ Correlates with a global sleep-related |

|---|---|---|---|---|
|  |  |  |  | QOL rating |

[a]Denotes the recommended measure.

*MID,* Minimal important difference; *OSA-18,* obstructive sleep apnea-18; *OSD-6,* obstructive sleep disorders-6 survey.

Adapted with permission from Quittner AL, Modi A, Cruz I. Systematic review of health-related quality of life measures for children with respiratory conditions. *Paediatr Respir Rev.* 2008;9(3):220–232.

### Recommendation.

The OSA-18 is recommended due to the established MID. However, more research on the internal consistency of this measure is warranted.

## Primary Ciliary Dyskinesia

Just recently, the first disease-specific HRQoL measures for primary ciliary dyskinesia (PCD) were developed. This is a rare, difficult to diagnose chronic respiratory condition and, thus, we utilized a collaborative approach to recruit patients and parents in North American (i.e., United States and Canada) and Europe. We developed four versions of the Quality of Life-PCD instruments (QOL-child, parent-proxy, adolescent and adult).[15,105] Although PCD shares some commonalities with CF, there are also important differences. For example, children with PCD often develop hearing problems due to chronic otitis media, which can lead to challenges at school (i.e., Individual Education Plans) and with peer relationships. In contrast, they are not pancreatic insufficient and therefore do not have the growth and digestive issues that are common among pediatric patients with CF.

All of these measures were developed using the FDA Guidance,[5] beginning with focus groups with stakeholders (e.g., pulmonologists, ear, nose, and throat (ENT) specialists, patients/parents), followed by open-ended interviews, content analysis, and cognitive testing of the draft instruments.[15,105] We developed a school-age measure for children ages 6 to 12 years, a parent-proxy measure for this age group, an adolescent measure for ages 13 to 17 years, and an adult version for those 18 years or older. The school-age version is a “speaking questionnaire” in which the computer/tablet asks the questions aurally with accompanying pictures. All measures take less than 10 minutes to complete and all have been developed and validated for electronic patient-reported outcomes (ePRO) administration; platforms including internet, tablet, and phone administration.

The preliminary measures for school-age children include 37 items, the parent proxy has 41 items, and the adolescent measure has 43 items. We are now performing international, psychometric validation studies of these measures and plan to reduce the number of items on each questionnaire once we have analyzed the items in relation to their scales. Generally, the domains represented on the pediatric measures, depending on respondent, include Respiratory Symptoms, Physical Functioning, Emotional Functioning, Treatment Burden, Ears & Hearing, Sinus Symptoms, Social and Role Functioning, Vitality, Health Perceptions, and School Functioning. Preliminary psychometric testing in the UK and North America indicate that these measures have good reliability (both internal consistency and test-rest reliability) and strong content, convergent and divergent validity (with the St. George's Respiratory Questionnaire [SGRQ] and the Sino-nasal Outcome Test [SNOT]). All versions of the QOL-PCD have now been translated into German, Danish, Dutch, Spanish, and Arabic. Further translations are planned.

There is an urgent, unmet clinical need for FDA/European Medicines Agency (EMA) approved medications for PCD, and given that it is unlikely that lung function will be a sensitive indicator of improvement in this population, the use of HRQoL measures as a primary or secondary endpoint is critical for clinical trials of new medications. The QOL-PCD measures have been designed to meet this need. In addition, these measures can be used to better understand this complex, rare disease including its course and progression, predictors of exacerbation, and long-term functioning.

## Recommendation.

To date, the newly developed QOL-PCD measures are the only disease-specific HRQoL measures to be developed. PCD is extremely rare and, thus, we developed these measures in both

North America and Europe. Their preliminary development and psychometric properties indicate they will become the "gold standard" for this population. We are in the process of translating these measures into multiple languages and they will be utilized soon to evaluate the benefits of a new medication for PCD.

## Conclusions and Future Directions

The shift in medicine toward a patient-centered model of care is consistent with the PRO guidance established by the FDA and guidelines written by the EMA.[6] The FDA Guidance outlines the steps needed for PRO development and highlights the importance of including the patient perspective in the evaluation of new pharmacological interventions. HRQoL instruments are one of the most commonly used types of PROs and provide a more comprehensive assessment of functioning across several domains (i.e., symptoms, physical, emotional and social functioning, treatment burden). This information is useful for both research and clinical purposes. These measures can improve patient-provider communication and care, track progression of disease and health outcomes, evaluate the efficacy of new pharmacological or behavioral interventions, and inform decision-making.

Several well-established HRQoL instruments exist for aerodigestive disorders, asthma, CF, bronchopulmonary dysplasia, primary ciliary dyskinesia, and sleep-related breathing disorders. There is a need to develop disease-specific HRQoL measures for other pediatric respiratory disorders, such as interstitial lung disease, lung cancer, and ventilator dependency. Previous research has utilized generic measures for these disorders.

In conclusion, HRQoL measures provide unique information on patient symptoms, level of functioning, and response to treatment. Inclusion of these instruments has been shown to facilitate patient-provider communication, detect problematic areas of functioning, and enhance shared decision-making. As technology advances, these instruments can be administered electronically on tablets, smart phones, or computers, which facilitates data entry and immediate scoring. Thus, use of these instruments is increasing in both clinical and research domains. Integration of HRQoL measures into clinical care is a critical step in promoting patient-centered care and quality of life.

## 14

# Transition From Pediatric to Adult Care

*Anna Bamford MBBS, Donald Payne MBBChir, MD, FRCPCH, FRACP*

## Introduction

Children and adolescents with chronic respiratory disease become adults with chronic respiratory disease. As a result of ongoing improvements in health care, this is now increasingly the norm rather than the exception. Therefore professionals who look after children and adolescents with chronic illness have a responsibility to consider how their patients' health care needs will continue to be met as they become adults. This chapter discusses the background to transition from pediatric to adult health care and provides a practical approach to assist health professionals, administrators, patients, and families to plan and negotiate the process.

## What Is Transition?

Transition, as defined by the Society for Adolescent Health and Medicine in the United States, is a “purposeful, planned process that addresses the medical, psychosocial and educational/vocational needs of adolescents and young adults with chronic physical and medical conditions as they move from child-centered to adult-oriented health care systems."[1] There is a wide range of chronic pediatric respiratory disorders that persist through adolescence into adulthood (Box 14.1). For some conditions, such as cystic fibrosis, models of transition are already relatively well established, with the existence of recognized specialist adult centers and clear pathways to facilitate the move from pediatric to adult care.[2–5] For other, rarer (e.g., primary ciliary dyskinesia) or more heterogeneous conditions (e.g., bronchiectasis), transition models are less well established.[6–8] Finally, there is an increasingly large cohort of adolescents and young adults growing up with respiratory disorders (e.g., chronic lung disease associated with extreme prematurity, muscular dystrophy, or ventilator-dependent airway malacia) with which adult health professionals may have had little or no clinical experience and minimal training.[9–11] These young adults may have associated co-morbidities, (e.g., significant neurologic disease or cognitive impairment) that present an additional challenge to ensuring a successful transition.

**Box 14.1**

### Pediatric Respiratory Disorders That May Persist Into Adulthood

- Cystic fibrosis
- Asthma
- Primary ciliary dyskinesia
- Other causes of bronchiectasis (e.g., immunodeficiency, postinfectious)
- Interstitial lung disease
- Chronic lung disease of prematurity
- Obliterative bronchiolitis
- Neuromuscular disorders (e.g., muscular dystrophy)
- Tracheomalacia/bronchomalacia
- Lung transplant recipients

# Why Is Transition Important?

Before outlining some of the practical steps involved in developing a transition plan, it is important to consider why the process needs to be addressed at all. Why should patients and families, who have developed a trusting and collaborative relationship with their health care providers over many years, have to leave this behind and develop a completely new set of relationships? There are a number of aspects to this question. These include acknowledging the process of adolescent development, the emerging health care needs and patterns of morbidity in adulthood, the differences between pediatric and adult models of care, and the views of patients and their carers.[12–14]

## Understanding Adolescent Development

For adolescents and young adults with a chronic respiratory disorder, the transition from pediatric to adult health care is just one of a number of transitions they will encounter. Adolescence refers to the developmental stage between childhood dependence and adult independence. During this time, individuals begin to establish their own identity and self-image and take on adult roles (Box 14.2).[15] Key tasks that adolescents and young adults usually complete include developing independence from parents or caregivers, forming relationships outside the family, and providing for themselves financially. Significant transitions during this period include leaving school and joining the workforce or enrolling in higher education, moving away from the parental home, and possibly becoming parents themselves. Health professionals who work with adolescents and young adults need to acknowledge and understand this process of adolescent development, and recognize that the transition from pediatric to adult health care occurs within the wider context of a more general transition from childhood to adulthood.

**Box 14.2**

### Tasks of Adolescence

- Separate from parents
- Develop a coherent sense of self
- Come to terms with physical self
- Come to terms with sexual self
- Develop mature altruistic relationships
- Develop financial independence

Seen within this context of increasing independence and autonomy, transition to adult care thus sends a powerful message to young people with chronic illness that they have a future and that they are expected to participate in and contribute to society as adults, which the majority of young people with chronic illnesses go on to do.[16,17] Remaining within the pediatric health care system may give the impression that living life as an adult is unlikely to be achievable. With increasing age and maturity, many young people become increasingly uncomfortable being cared for in a child-centered setting. A danger of not addressing the transition to adult care is that they may become lost to follow-up when they decide for themselves that they have outgrown their pediatrician.

It is also important to be aware that some young adults with chronic illness (e.g., those with muscular dystrophy, severe neurologic impairment, or who are ventilator dependent) will never be able to attain the same degree of independence as that achieved by their healthy peers. However, this does not mean that these young adults should be looked after within a pediatric model of care indefinitely. There are many ways to acknowledge a young person's development into adulthood (seeing them on their own, discussing age-appropriate topics, providing them with opportunities to be involved in decision making), even if their physical independence is limited. These issues are discussed in more detail later in the chapter. For young adults who are physically dependent on others for providing aspects of their care, one obvious example of emerging adulthood can be seen when this assistance is no longer provided by parents but by other adults (e.g., friends or partners).

## Adult Health Care Needs and Patterns of

## Morbidity

Pediatricians are trained to deal with children and, increasingly, with adolescents.[18] However, few are trained to provide care for adults. In the same way as pediatricians recognize that it is inappropriate for adult-trained physicians to manage young children, it also becomes increasingly inappropriate for pediatricians to continue to care for their patients once they have completed the tasks of adolescence and are living their lives as adults. While pediatricians may feel relatively confident and competent managing certain disease-specific aspects of respiratory disorders, such as asthma or bronchiectasis, more general areas of adult health care (e.g., sexual and reproductive health, cardiovascular problems, or liaison with employers) are likely to be less well managed. There are some clinics (e.g., for cystic fibrosis) in which the same team provides care for children, adolescents, and adults. However, in the interest of optimal health care, it is important that whatever model is employed, professionals who manage adults with chronic respiratory disease receive adequate training in general adult health issues. Adult-trained physicians may be more likely to address issues, such as fertility, teratogenicity of treatments, and the importance of genetic counseling, which pediatric physicians may not be as comfortable discussing.[19,20]

## Differences Between Pediatric and Adult Models of Care

Logistical and financial considerations also come into play when considering transition. Pediatric and adolescent medical departments are not designed or funded to provide care for adults. Budgets are limited, and staffing, equipment, and hospital systems are designed to provide high-quality and developmentally appropriate care for infants, children, and adolescents rather than adults. Therefore at some point, a decision must be made to transfer adolescents and young adults with chronic illness to a unit that can provide developmentally appropriate care.

Traditionally, the adult model expects patients to take responsibility for their own care. If they do not attend for regular outpatient review, they are less likely to be contacted and followed up than if they are being managed within a pediatric setting. A challenge for adult physicians is to recognize and understand that adolescents and young adults are still developing and that they may continue to need a greater degree of involvement by the health care team, at least for the first few years after transfer.

## What Is the Evidence Base for Transition?

Over time, a number of principles regarding the transition process have been developed, which have gained widespread consensus.[21–25] A number of studies have highlighted problems associated with unsuccessful transition from pediatric to adult care, in different subspecialty areas. These include unexpected transplant rejection following transfer to adult care in young adults who had received renal or liver transplants in childhood,[26,27] and the deaths of young adults with congenital heart disease who were cared for by clinicians lacking specific training in the management of these conditions.[28] The absence of an appropriately trained adult team is a significant barrier to successful transition, as discussed later in the chapter. Less extreme consequences of unsuccessful transition to adult care include the loss of young adult patients to follow-up, frequent missed appointments, and deterioration in disease control.[29–31] For young people with chronic respiratory disease, there is a very real possibility that lack of regular contact and follow-up with the medical team over a number of years can result in a major and potentially irreversible deterioration in lung function and quality of life.[32]

The evidence base for particular transition programs is small. What evidence there is suggests that having planned transition activities for chronic disease is preferable to none at all, with improvements in adult clinic attendance, disease control, and fewer complications when there are pathways in place. Cole et al. (2015) implemented a transition service for young people with inflammatory bowel disease, which resulted in decreased admissions and need for surgery, and improved adherence to medication and clinic attendance following transfer to adult health care, compared with those who did not go through the program.[33]

In young people with type 1 diabetes, establishing a formal transition pathway has been shown to improve adult clinic attendance, HbA1c measures, and patient and carer satisfaction.[34,35] In chronic respiratory disease, the most substantial evidence relates to the transition of young people with cystic fibrosis. Progressing through a transition program, or at least the introduction of the adult team prior to transfer, has been shown to reduce patient and parent concern regarding transition to an adult service.[36–38] Gravelle and colleagues evaluated three components of their transition program—a clinical pathway, a joint pediatric and adult pregraduation workshop for patients, and a readiness for transition scale delivered to young people about to graduate from pediatric services. The combination of these interventions led to improved identification of deficits in patient knowledge and improved patient understanding of the adult care system and confidence for transition.[39] In terms of disease outcomes, one study found that young people appropriately transferred to adult care had a less rapid decline in lung function, compared with disease severity–matched patients who remained in pediatric care centers.[40] Duguépéroux and colleagues have described outcomes for young adults with cystic fibrosis 1 year after transfer to an adult center and demonstrated that the clinical status of the patients transferred remained stable, with an increase in the mean number of outpatient attendances in the year after transfer to the adult center, compared to the year before.[41]

## Transition: A Practical Approach

Transition refers to the process of preparing adolescents and young adults for the move to the adult health care system and to an adult health team. It is widely acknowledged that this is a continuous process leading to the single event of transfer of care. The transition process needs to be planned in advance and begin early. While there are certain elements of transition that are disease-specific, there are many aspects that are generic to all chronic illness. Russell Viner, a leading advocate for adolescent and young adult health in the United Kingdom, has summarized the approach to transition as follows[42]:

- Prepare young people and their families well in advance for moving from pediatric to adult services
- Ensure that they have the necessary skill set to survive and thrive there
- Prepare and nurture adult services to receive them
- Listen to young people's views

## Preparing Young People for Transition

Preparing young people and their families for transition involves discussing the process with them early. Some suggest making transition a topic of discussion from the moment of diagnosis. In practice, this may prove difficult, given the amount of information that families have to take in at the time of diagnosis of a chronic illness. However, the prospect of transition to adult care is an issue that needs to be brought up in any discussion of long-term prognosis—a subject that usually arises in conversations at an early stage. For older children and adolescents, there is no "right" time to start increasing the focus on transition. However, the consensus is that the emphasis on transition should increase as children enter adolescence, often at the same time as they move from primary to secondary school. Transition is one aspect of the wider process of providing developmentally appropriate health care for adolescents. Health professionals can employ certain practical strategies to help promote healthy adolescent development and prepare adolescents for their subsequent move to adult care. These strategies include the following:

- Seeing adolescents on their own, separate from their parents, for part of the consultation
- Emphasizing the importance of confidentiality
- Discussing their understanding of their illness and actively promoting self-management

- Addressing general adolescent health issues, in addition to those related to their specific condition

Seeing adolescents alone for part of the consultation is a visible way of demonstrating to them and their families that adolescence is a time of developing independence. It conveys a message to the whole family that it is appropriate for the adolescent to begin to take increasing responsibility for his or her own health.[43] A major advantage of seeing adolescents alone is that it increases the chance that they will talk. Asking questions about school, friends, and activities shows an interest in the adolescent as an individual, rather than in his or her disease. This allows time for a rapport to develop and provides an opportunity to see how the young person's illness fits in with the rest of his or her life—in particular, whether or not the adolescent sees his or her condition and its treatment as a priority.

Box 14.3 shows the Home, Education, Eating, Activities, Drugs, Sexuality, Suicide, Safety (HEEADSSS) framework, used widely around the world, which is a helpful guide for clinicians to use when interviewing adolescents.[44] HEEADSSS begins with relatively unthreatening questions about home, school, and activities. These have the dual purpose of gathering information and allowing time to develop rapport. However, difficulties in these areas (e.g., prolonged school absence, no hobbies or interests) may be a reflection of poor disease control or other underlying problems, such as anxiety or depression. As discussed later in the chapter, mental health problems and health risk behaviors, such as smoking, alcohol, and other drug use, are common in adolescents with chronic illness and always need to be considered.[45–47] It is essential that such a risk and protective health screen is used at the outset of adolescence and is continually revisited and updated.

**Box 14.3**

## The HEEADSSS Framework

### H Home

- Where do you live? Who lives with you?
- What are relationships like at home?
- Who would you talk to if you had a problem?

## E Education (or Employment)

- Which school do you go to? Which year are you in?
- Which subjects do you enjoy? What are you good at?
- Who do you spend time with at school? What are the teachers like?
- Is your school a safe place?

## E Eating

- Does your weight or body shape cause you any stress?
- Has there been any change in your weight recently?

## A Activities

- What do you enjoy doing outside of school?
- Are you in any clubs or sports teams?
- Who do you meet up with at weekends?
- Do you see your friends mostly in person or catch up online?
- Some young people tell me they spend a lot of time online. What sort of things do you use the internet for?
- How many hours per day do you spend using screens (computer/television/phone)?

## D Drugs

- Do any of your friends or family smoke cigarettes or drink alcohol? How about you?
- How much do you smoke/drink? Every day? On weekends?
- Have you ever tried marijuana or other drugs not prescribed to you?

### S Sexuality

- Are you interested in boys, girls, or both? Are you not yet sure?
- Have any of your relationships been sexual relationships?
- What do you understand by the term “safer sex”?

### S Suicide

- Do you feel stressed or more anxious than you would prefer to feel?
- Do you have any trouble with your sleep pattern?
- How would you describe your mood? Do you ever get really down?
- Some people who feel really down often feel like hurting themselves or even killing themselves. Have you ever felt like that?
- Have you ever tried to hurt yourself?

### S Safety

- Is there any violence at your home or school? Do you feel safe at home?
- Have you ever met (or planned to meet) with anyone whom you first encountered online?
- Have you ever been seriously injured? How? How about anyone else you know?

From Klein D, Goldenring J, Adelman W. HEEADSSS 3.0: the psychosocial interview for adolescents updated for a new century fueled by media. *Contemp Pediatr*. 2014:31:16-28.

## Establishing Confidentiality

When seeing adolescents on their own, it is essential to explain at the outset that the conversation will remain confidential and that, while you may have to consult with colleagues, information will not be discussed with parents, without the adolescent's permission. The limits of confidentiality must also be made explicit. The disclosure of any activity that puts the young person at serious risk of significant harm (such as suicidal thoughts or physical/sexual abuse) cannot remain confidential. Neither can the disclosure of activities that put others at risk. If adolescents are assured of some degree of confidentiality, they are more likely to speak frankly.[48] In practice, this increases the chances of being able to address issues that can have a major impact on disease control (e.g., treatment adherence, smoking, and anxiety), thus opening up the real possibility of providing effective health care.[49]

## Actively Promoting Self-Management

Self-management of chronic disease is a major focus of adult programs. Pediatricians can assist in helping adolescents to develop self-management skills through the gradual process of increasing the focus on the adolescent, rather than their parents, during each consultation. As mentioned earlier in the chapter, this is helped by seeing adolescents on their own. Discussions should focus on the understanding of their illness, their priorities and goals, the reasons for and the effects of adhering to a specific treatment regimen, and ways to minimize the impact of the illness on their day-to-day life. Over time, other practical issues can be discussed. These include how to book or reschedule an appointment, obtaining prescriptions and knowledge of any fees payable, whom to contact in an emergency, and how to get to the adult clinic (e.g., public transport, parking). These are issues common to all chronic illnesses and, when addressed, can help to reduce the anxiety around the eventual transfer of care to an adult center.[38] To assist in this process, many transition programs have developed checklists that patients and professionals can use to track each individual's progress through adolescence and identify issues that may need to be addressed at specific times. An example is shown in Box 14.4, and others are available on the transition websites listed in the Suggested Reading at the end of the chapter.[22,23] There is new evidence for the use of other technology to encourage self-management and assist with transition, such as scheduled mobile phone text messages, web-based programs, or online contact with transition mentors.[50–52]

**Box 14.4**

## Transition Readiness: Sample Checklist for a Young Person Aged 15 to 16 Years

### Independence

Sees health professional alone for some of the consultation
Understands about confidentiality (and its limits)
Feels comfortable asking questions during the consultation

### Awareness of Transition and Transfer

Understands that transfer to the adult center will occur within the next 2 to 3 years
Understands some of the differences between pediatric and adult health care
Knows which adult center he or she will be going to and where it is

### Self-Management

Understands his or her medical condition and can explain it to a friend
Understands his or her treatment regimen (what the treatments do, why they are important, and the side effects)
Able to administer own medication/treatment
Able to discuss any difficulties with adherence to treatment
Knows whom to contact in an emergency
Beginning to know how to make appointments, obtain new prescriptions

### General Adolescent Health

Able to discuss body image, healthy eating, exercise
Has discussed sexual health/fertility with his or her doctor
Has discussed alcohol, smoking, and other drug use—impact

on their health
Able to discuss mood (anxiety, depression)
Able to identify support systems outside the family and how to access psychological support if required

### Educational and Vocational Planning

Has discussed school, plans for the future
Able to discuss any difficulties at school (attendance, bullying, subject difficulties)

## Addressing General Adolescent Health Issues

Health professionals who work with adolescents need to acknowledge and understand the process of adolescent development and be aware of both the impact of emerging adolescent behaviors on disease management, as well as the effect of a chronic respiratory disorder on normal adolescent development.[53,54] Regular appointments and hospital admissions, time off school, limitation of normal activities, and reduced ability to interact with peers can inhibit an adolescent's path toward independence. Parents may also find it difficult to let go. Therefore it is important that health professionals monitor their patients' progress through adolescence and identify problems when they arise.

Certain features of adolescence, such as engaging in exploratory behaviors (e.g., smoking, drug use) and challenging authority (e.g., reluctance to adhere to a regular treatment regimen, nonattendance at appointments), may lead to poor disease control.[45] The available data suggest that adolescents with chronic illness are just as likely, or even more likely, to engage in health-risk behaviors as their healthy peers.[45–47,55] The effects of certain behaviors, such as smoking, on health outcomes are more pronounced in adolescents with chronic respiratory disease than in those without.[43,56] Adolescents with chronic illness are more likely to suffer from anxiety and depression, which may also have a considerable impact on health outcomes and on a young person's ability to manage their illness.[57,58] Health professionals need to develop confidence in discussing health-risk behaviors and mental health problems with their adolescent patients and be able to offer support along with access to more specialized services (e.g., clinical psychology or psychiatry) when appropriate. In support of this approach, a study in primary care involving adolescents 11–16 years of age demonstrated that adolescents had more positive perceptions of their primary care physician when sensitive issues, such as drugs, sex and mental health, were discussed.[59] The adolescents studied were also more likely to take an active role in their treatment if the consultation included the discussion of these types of sensitive topics.[59]

Providing this level of care for adolescent patients requires that systems be organized to facilitate the process, such as scheduling longer appointment times for young people. This has significant implications for the provision of appropriate resources. However, taking a long-term view, the argument for providing intensive input during adolescence and young adulthood is that this will lead to improved health outcomes and reduce the potential for unscheduled emergency visits and hospital admissions, which account for the majority of the health care costs associated with chronic illness.

## Preparing Adult Services to Receive Young People With Chronic Respiratory Disorders

A successful transition requires there to be an adult service that is willing and able to receive young people with chronic illness and to provide high-quality care. For cystic fibrosis, the existence of specialist adult centers is well established, and the models of transition are those to which other subspecialties often look for guidance. Transition programs for asthma, a much more common condition than cystic fibrosis, are less well established, probably because most young adults with persistent asthma do not require the same level of specialist, multidisciplinary input as young adults with cystic fibrosis.[60] However, for children and adolescents with severe or treatment-resistant asthma, transition and transfer to a specialist adult center will be required.[61]

For young adults with rarer conditions, the challenge for pediatric health professionals is to identify suitable colleagues in the adult system that have the skills and training to provide ongoing care. The absence of suitable providers is one of the reasons why some patients may remain under the care of the pediatric team indefinitely. For example, the increasing number of young people dependent on ventilatory support now reaching adulthood creates a challenge for their transition.[62] In the longer term, one of the many roles for pediatricians to play is that of advocate for the provision of suitable training programs for adult physicians. Adolescent medicine is an accredited specialty in the United States, Canada, and, most recently, Australasia.[63] Good communication, collaboration, and respect between pediatric and adult units are essential. Depending on the availability of services and personnel, different models of transition and transfer may develop. One option is the establishment of a regular joint clinic for adolescents and young adults, involving both pediatric and adult teams, which may be based either at one center or the other, or rotate between the two. Another model is for patients to have one or two appointments at the adult center while still being seen at the pediatric center prior to the eventual final transfer of care to the adult center. With this type of arrangement, it is important to make clear who should be the first port of call in an emergency. There is no evidence that any one model is superior to another, and, in practice, the model developed will depend on a variety of factors. These include the number of patients to be transitioned and the availability of appropriately trained staff, funding, and clinic space. More important than the precise model of transitional care employed is the need for all health professionals who work with adolescents and young adults to recognize and understand the process of adolescent development and to incorporate this into their day-to-day practice.

## Listening to Young People's Views

It is vital to involve adolescents and young adults in the transition process.[42] Transition is often an unsatisfactory experience for young people, as well as for their parents or carers. Often they report that the process is uncoordinated, complicated, and anxiety provoking, and that they feel lost and unprepared for moving to an adult service, particularly if the move is sudden.[12,64] On the other hand, young people do appreciate the relative independence and increased responsibility expected of them in the adult service if supported appropriately.[12] Engaging with young people to develop or improve processes means ensuring that they not only participate actively in their own individual transition and transfer to adult care but also that they can contribute to effective planning and implementation of the wider program of transition.[65] The Royal College of Paediatrics and Child Health in the United Kingdom has published guidelines to promote the participation of children and young people in the planning of health services.[66] Transition programs are much more likely to be successful if they incorporate the views and ideas of the young people they are designed to support, and it has been shown that feeling less involved in their health care results in poorer disease outcomes in adolescents and young adults.[67]

Providing a suitable environment, considering both the physical space characteristics and the staff attitude and values, is also important.[68] Too often, young people report that they feel like they do not belong in either pediatric or adult care, with the pediatric setting feeling paternalistic and too controlling, and the adult service overwhelming, impersonal, and unwelcoming.[69] It is essential to engage with young people in the design and style of clinical areas as well as how the service operates. This is likely to increase the chances of them remaining engaged in their own health care.[66] Simple measures can be very effective, such as considering the color scheme of the clinic area, the furniture, and the reading material available (e.g., age-appropriate magazines and health promotional literature).

## Barriers to Transition

In addition to the participation of adolescents and young adults in the process, successful transition requires health professionals to advocate continually for the needs of this group and for the provision of adequate services. As mentioned earlier in the chapter, a major barrier to successful transition is the absence of appropriately trained health professionals within the adult health care system.[28] Where adult services are lacking, pediatricians need to provide training for their adult colleagues, while adult health professionals need to acknowledge and embrace the need to provide a clinical service for the increasing number of young adults with chronic respiratory disorders who will be moving to adult care. This process also needs the support of the health service administrators and politicians who control the funding. Above all, it requires a shift in attitude and culture of all concerned in order to recognize and understand the importance of adolescent and young adult health.[70]

Where adult services do exist, mutual trust and respect between the pediatric and adult centers is important; a lack of these qualities may hamper transition. Guidelines for transition recommend that a nominated individual is identified who is responsible for the overall transition process (a transition lead or coordinator).[23] This role may be performed by any member of the health care team. The coordinator should ensure that all aspects of the process have been considered and follow up on any difficulties encountered. One of the coordinator's roles should be to facilitate communication between the pediatric and adult centers and to provide a written summary of the young person's condition in advance of the transfer date. Financial considerations and health insurance coverage are also key issues.[60] With increasing age, the rules regarding eligibility for certain services and allowances may change. For example, financial support or equipment, which is provided during childhood and adolescence, may not be available indefinitely. These issues need to be anticipated well in advance.

## Summary

Transition from pediatric to adult care is one aspect of the wider provision of health services for adolescents and young adults. An understanding of the health issues affecting this group along with specific training in adolescent and young adult health is essential for all health professionals. The number of young adults with chronic respiratory disorders of childhood is only going to increase, as will the range of specific disorders that adult physicians will need to be competent to manage. For pediatric and adult respiratory physicians, the clinical landscape is changing. The challenge is there to be met.

# Long-Term Consequences of Childhood Respiratory Disease

*Andrew Bush MB BS(Hons), MA, MD, FRCP, FRCPCH, FERS, Peter Sly MBBS, MD, FRACP, DSc*

## Introduction

For too long, pediatricians and adult respiratory physicians have operated within developmental silos to the detriment of both and, more importantly, to the detriment of children. There are four reasons why better interactions between pediatricians and adult chest physicians are crucial for lung health. First, early life, pregnancy, and even preconception factors impact adult lung function and health; second, new chest diseases are coming to adult chest clinics as a result of advances in pediatric respiratory care, the classical disease being the survivors of prematurity; and third, children with diseases conventionally the province of the pediatrician (e.g., cystic fibrosis [CF], Duchenne muscular dystrophy) are now surviving into adult life, and pediatricians need to educate their adult colleagues about these new issues. Finally, adult physicians have very large cohorts from which we can learn in pediatrics; for example, the increased risk of respiratory infections in adults treated with inhaled corticosteroids (ICS) sounds a warning note in pediatric practice.[1–4]

An illustration of the danger of working in silos is the first figure in the classical Fletcher and Peto paper[5] showing the trajectories to chronic obstructive pulmonary disease (COPD), which could be called the "Star Trek" figure, the adult beamed down with a normal forced expired volume in the first second ($FEV_1$), with no concept that early life was of any relevance or even existed. In fairness, their second figure did acknowledge the possibility of failure to reach the full potential of lung development, but even today, we suspect that this is mere lip service for many.

Two recent papers have shown how interactions between pediatric and adult studies can build understanding of pathophysiology. The adult study finally nailed that COPD is a disease set up in childhood and that adult factors divorced from an understanding of pediatric risk factors are irrelevant; specifically, smoking is neither necessary nor sufficient for the development of COPD. A large study combining three adult cohorts[6] defined two pathways to COPD, contributing equally to the burden of the disease: normal spirometry at age 40 years, with accelerated decline thereafter, and low $FEV_1$ at 40 years with a normal rate of decline. Of those not attaining the normal plateau (determined before adult life, see below) 26% developed COPD at follow-up, whereas if a normal plateau was reached, the risk was 7%. Neither from this nor any of the other four major studies reporting decline in lung function[6–9] over time was there any consistent adult factor identified that was associated with accelerated decline. The pediatric paper was a follow-up of the Childhood Asthma Management Program (CAMP) asthma study participants,[10] in whom annual prebronchodilator and postbronchodilator spirometry was performed into the third decade of life. Roughly equal proportions had a normal growth pattern and normal rate of decline, a normal growth pattern with accelerated decline, reduced growth with normal rate of decline, and both reduced growth and reduced rate of decline, interestingly a category not found in the COPD paper. Clearly, more follow-up data is needed to be sure this is a true decline rather than a transient dip in growth. This discrepancy may be related to the fact that the COPD study recruited all comers, and this last trajectory may have been missed because there were insufficient asthmatics; in other words, this last trajectory may only be seen in asthmatics, which hypothesis requires further confirmation.

Further underscoring the importance of pediatric factors in adult lung disease, a European study[11] identified five markers of childhood disadvantage (maternal asthma and smoking, paternal asthma, and childhood asthma and severe respiratory infections), which in combination were associated with worse adult $FEV_1$, a steeper rate of decline in $FEV_1$, and increased COPD risk, at least as strong a signal as smoking. The conclusion is stark and unavoidable; if COPD is to be prevented, it is too late to start thinking about this in adult life.

Part of the difficulty of understanding the developmental perspective of adult diseases is that recall of childhood events by adults is notoriously unreliable; in one study, the incidence of pertussis and pneumonia (two fairly major pediatric respiratory illnesses!) was recorded prospectively.[12] False positive and negative recall was very common (Table 15.1), and the message is that retrospective recall may not be reliable. Similarly, so-called newly diagnosed asthma at age 22 years in 49 of 161 asthmatics diagnosed at all ages in the Tucson study was predicted by bronchial hyperresponsiveness and low lung function at age 6 years.[13] Even the limited information that can be recalled is often not sought; in one survey, very few adult physicians asked about early life events.[14]

## Table 15.1

**High Prevalence of False Positive and False Negative Recall in Adult Life of Childhood Pneumonia and Pertussis**

| | Pneumonia | Pertussis |
|---|---|---|
| Prospective parental report in first 7 years of life | N = 195 | N = 215 |
| True retrospective recall in adulthood | 106/193, (55%) | 77/215 (36%) |
| False retrospective recall in adulthood | 53/159 (33%) | 74/151 (49%) |

Johnston ID, Strachan DP, Anderson HR. Effect of pneumonia and whooping cough in childhood on adult lung function. *N Engl J Med*. 1998;338:581-587.

There are, however, important caveats when assessing the role of potential risk factors for long-term adverse outcomes; probable pathways are shown in Box 15.1. Most often, it is not possible to untangle these possibilities, especially in the context of multiple interlinked exposures (e.g., increased risk of smoking, increased pollution exposure, living where there is a lot of neighborhood violence, reduced rate of breast-feeding all linked to low socioeconomic status [SES]). It is impossible to consider the long-term consequences of childhood disease without considering the long-term consequences of those factors underlying disease, some of which are discussed in more detail in earlier chapters in this book. However, the mantra that association does not prove causation should always be remembered. Causation can be demonstrated by intervention studies, or the likelihood bolstered by demonstration of biological plausibility by laboratory studies.

**Box 15.1**

## Pitfalls in Ascertaining Causation Between Exposure and Outcome

- The exposure is causative of the disease (disease would not happen without the exposure)
- An exposure may be causative of disease, but it is masked by other effects, for example, the interactions between cigarette smoke and glutathione transferase polymorphisms
- The underlying cause of being exposed is itself the reason for the association and not the exposure itself
- The exposure makes the disease manifestation worse but is not actually causative
- Treatment of the consequences of the exposure, but not the exposure itself, causes the disease
- An unknown underlying factor causes both the exposure and the disease; a good example of this is antibiotic prescription to infants, as discussed in more detail below
- The exposure is merely a marker for an unknown underlying

exposure factor that causes the disease

- Berkson's bias (a selection bias leading to hospital cases and controls in a case control study to be systematically different because the combination of risk exposure and occurrence of disease increases the likelihood of hospital admission). In other words, the harder you look in a selected population, the more you will find.

New diseases and the more prolonged survival of children with “childhood” diseases make cross-developmental interactions ever more important. Survivors of preterm birth have fixed and variable airflow obstruction,[15–18] but no evidence of eosinophilic airway inflammation[19,20] and are not helped by ICS.[21] It is essential that adult physicians understand this is different from atopic asthma (and probably also COPD later in life) and needs different approaches. The increased longevity in CF has led to the importance of reduced bone mineral density and insulin deficiency being appreciated, which has in turn meant that pediatricians diagnose and treat these complications early. The next challenge will be the high prevalence of colonic malignancy[22] and whether any childhood management strategies can reduce this risk.

## How the Lung Develops in Health and Disease

Knowledge of normal lung development is essential if the long-term consequences of disease are to be understood. This is covered in detail elsewhere, so is only briefly summarized here. Interestingly, there is increasing evidence of adverse, preconception, transgenerational effects on the fetus. Thus, two studies have suggested that grandmaternal smoking increases the risk of her daughters' children having asthma even if the daughters themselves never smoked.[23,24] This has been attributed to epigenetic mechanisms, but it is not easy to reconcile this explanation with the mammalian germline reprograming that removes epigenetic signatures immediately after fertilization.[25] The effect is not accounted for by the increased risk of asthma in the daughters of smoking mothers. Clearly, more work is needed to understand the mechanisms of these transgenerational effects and to determine if other adverse insults such as pollution may have the same effect.

## Normal Antenatal Lung Development

This is described in more detail in Chapter 2. The embryonic phase lasts from 0 to 7 weeks of gestation, and the primitive lung buds are outpouchings from the primordial gut. An anterior diverticulum appears at 4 weeks, the diverticulum bifurcates at 5 weeks, and lobes and segments become delineated thereafter. The main pulmonary arteries develop during this time, and blood vessel development follows the airways. From an early stage, there is phasic airway contraction and relaxation that are thought to be important in growth factor release. During the pseudoglandular phase, from 6 to 17 weeks, all generations of airways and their accompanying vessels are laid down, the latter by vasculogenesis (*de novo* blood vessel formation); thereafter airways increase in size but not number. From 16 to 26 weeks is the canalicular phase, during which time, the acinar structures form, surfactant synthesis in type 2 cells becomes apparent, and the respiratory barrier thins. True alveoli and their accompanying blood vessels first appear in the saccular phase from 26 to 35 weeks; the vessels develop by angiogenesis (outsprouting from existing vessels) and the alveoli develop by secondary septation. The details of the molecular pathways and genetic control of these processes are beyond the scope of this chapter; the reader is referred to recent reviews and manuscripts.[26–28] Important in this scheme is that adverse influences on airway branching are active in the first trimester and those active on airway caliber in the second and third trimester of pregnancy; and anything that interferes with the normal airway branching pattern will by definition adversely impact on the final alveolar numbers.

## Adverse Effects Across the Life Course: Introduction

Although it is convenient to separate adverse influences into discrete developmental blocks such as antenatal, childhood, and adult life, this is to some extent artificial, since environment across the developmental stages is closely linked. A recent study attempted to take a more holistic look, spanning pregnancy and infancy. They reported that in adjusted analyses, there was a dose-dependent increased risk of subsequent asthma with maternal urinary tract infection and maternal and infant antibiotic use and a decreased risk if there were more older siblings at home.[29] Delivery by Caesarean section increased the risk of subsequent asthma. The greater the number of risk factors, the greater the risk of asthma. However, these are all associations and are discussed in more detail below.

## Adverse Effects Operating Antenatally

There are four main mechanisms whereby antenatal insults may impact on long-term outcomes, both disease in childhood and subsequent adverse effects in adult life. These are by leading to abnormal lung structure by causing abnormal immunological function and indirectly by causing either or both low birth weight and prematurity. The fourth mechanism, fetal programming, has been much less studied in humans, but there is evidence that early and discrete adverse exposures in animals prime adulthood responses to allergens and infections.[30,31] A challenging human study showed that adult survivors of primary pulmonary hypertension of the newborn had much greater hypoxic pulmonary hypertensive responses than controls.[32] It is of course impossible to be certain whether this relates to fetal programing or different developmental manifestations of some unknown underlying condition.

### Tobacco and Nicotine Exposure

These are the most studied adverse influences. Structural changes have been most studied in animal models; of note, nicotine itself is damaging, calling into question the safety of e-cigarettes, nicotine patches, and nicotine chewing gum during pregnancy. Either may be safer than cigarettes, but this is unproven, and they certainly cannot be considered harmless.

Nicotine exposure in pregnancy has been shown to lead to airway remodeling, with increased deposition of type 1 and 3 collagen, airway lengthening and narrowing, airway wall thickening, and loss of alveolar tethering points leading to airway instability.[33–35] The airway wall may be thickened postnatally.[36] There is also increased MUC5AC expression in bronchial epithelial cells.[37] The postnatal functional readout of these structural changes is airway hyperresponsiveness (AHR) even in the absence of allergen exposure.[34] This is of particular importance, since three cohort studies[38–41] have shown that AHR in the newborn period, long before there is any evidence of airway infection or inflammation,[42] is associated with long-term adverse respiratory outcomes. Children of mothers who smoke are more likely to have asthma, and more likely to smoke themselves, thus perpetuating the cycles of avoidable damage to the lungs.[43] Finally, tobacco exposure may lead to premature emphysema,[44] with reduction of secondary septation and enlargement and simplification of alveoli; the relative contributions to this worrying effect of antenatal and postnatal smoke exposure have not been determined. Tobacco exposure of pregnant women is associated with a number of alterations in cord blood, including an increased responsiveness to allergens of cord blood mononuclear cells, abnormal Toll-like receptor function, and abnormal cytokine responses with a readout of increased viral wheeze in the first year of life.[45–48] The effect of maternal smoking on infant atopy is controversial with some finding no effect at all.[49] However, recently[50] an association between maternal smoking and food allergy and also with atopic dermatitis[51] has been reported, and a recent meta-analysis confirmed an association with atopy.[52] The mechanism may be via reduction in cord blood regulatory T cells (Tregs).[53] Finally, that active smoking is associated with prematurity and low birth weight has long been known; new data also shows that reduction of passive smoke exposure leads to reductions in preterm delivery.[54]

## Antenatal Effects of Pollution

There is increasingly compelling evidence that exposure of pregnant mothers to environmental pollution may adversely impact the fetus. In a study from Spain, the developmental residential exposure to benzene and nitrogen dioxide was related to spirometry at age 4.5 years in 624 children. There was a dose-dependent reduction in spirometry with increasing exposure levels in pregnancy but no other time point. This was worse for allergic children and those of low SES.[55] In another study of 736 North American children, mostly ethnic minorities, but also mostly nonsmokers, there was an association between $PM_{2.5}$ exposure levels between 16 and 25 weeks of gestation and the development of early childhood asthma; however, this result only appeared in boys.[56] It is likely that there will be adverse effects on the fetus of maternal biomass fuel exposure during pregnancy, but this has yet to be determined.

## Maternal Malnutrition and Obesity

It is a shameful commentary on the human condition that maternal malnutrition is still an issue in the 21st century. The best-known long-term data are from the Dutch famine lasting 5 to 6 months at the end of the Nazi occupation in the Second World War.[57] Famine exposure in the first and second trimester of pregnancy was associated with wheezing, but not airflow obstruction or increased atopic sensitization at follow-up in adult life; wheezing remained significant after adjusting for relevant confounders, and wheezing was independent of birth weight in this group (famine-born babies were on average 250 g lighter, a fairly small effect). An important follow-up paper demonstrated that not merely was there more wheezing illness at age 50, but also more coronary heart disease, hyperlipidemia, altered clotting, and obesity after early gestational exposure to famine.[58] Microalbuminuria and decreased glucose tolerance were reported in those exposed to famine in late gestation.

Maternal obesity is likely to become ever more common. Prepregnancy obesity is associated with early wheeze and asthma in the offspring.[59–62] There is no doubt that pregnancy obesity (which is of course closely linked with prepregnancy obesity) increases the risk of obstetric complications, but is also associated with wheeze in infancy and childhood. In a cohort study in which more than 38,000 mother-baby pairs were identified, maternal obesity in pregnancy was also associated with wheeze in the first 18 months of life in the baby[63]; this was confirmed by a pooled analysis of more than 85,000 mother-child pairs.[64] Risk increased linearly with body mass index, and the risk was not mediated via obstetric complications, prematurity or low birth weight. In another study of more than 6000 mother child pairs, prescription of inhaled bronchodilators in the first 4 years of life was associated with prepregnancy obesity.[65]

## Antenatal Effects of Acetaminophen?

There is ongoing controversy about whether acetaminophen given to mothers in pregnancy or to infants postnatally is associated with the development of asthma.[66,67] A recent murine model in which acetaminophen was given using various regimens to pregnant mice, lactating mice, and mouse pups, alone or in any combination, and no effect could be shown on the development of murine allergic airways disease.[68] A recent birth cohort study showed an association between acetaminophen use in both the first and last trimesters of pregnancy and subsequent wheeze in the offspring. However, this disappeared when adjusted for confounding factors, and there was no association between acetaminophen use for noninfectious reasons and subsequent wheeze.[69] However, given there are other available antipyretic and analgesic medicines such as ibuprofen (the safety of which has not been challenged), it would seem prudent to avoid acetaminophen in pregnancy and childhood.

## Maternal Hypertension?

Maternal hypertension in pregnancy has also been associated with an increased risk of wheeze,[70,71] although this has recently been challenged in the Avon Longitudinal Study of Parents and Children (ALSPAC) study.[72] They found that maternal hypertension before pregnancy, but not gestational hypertension, was associated with subsequent childhood wheeze, but even this association needs replication.

## Maternal Antibiotic Use?

Antibiotic prescription in pregnancy has been associated with subsequent wheeze,[73–75] and certainly in a murine model, antibiotic use in pregnancy affects adaptive antiviral immune responses via alterations in the pup's microbiome.[76] However, a recent birth cohort study has clarified the association. Maternal use of antibiotics in the first trimester was not associated with wheeze; in the last trimester, there was an association with wheeze, and this remained, albeit weakly, when adjusted for confounding factors. Genitourinary infection in pregnancy increased the risk of subsequent wheeze in the offspring, irrespective of antibiotic treatment. No mechanisms for these possible associations were defined.[77]

## Maternal Stress in Asthma—A Developing Field

There is increasing evidence that maternal stress (in the very broadest sense) is important in disease outcomes, in particular, asthma. There are extra pitfalls in determining this relationship (Box 15.2).

**Box 15.2**

### Special Pitfalls in Determining the Relationship Between Maternal Stress and Asthma

- Does stress *per se* cause asthma? This could be made more complicated if there is a time delay between the onset of stress and the onset of asthma.
- Does stress lead to overinterpretation of symptoms? Or lead to symptoms as a shield, or symptoms as a manifestation of stress?
- Does stress lead to symptoms that are misdiagnosed as asthma; the obvious examples are dysfunctional breathing and vocal cord dysfunction?
- Do stress-associated behaviors (e.g., smoking) cause symptoms?
- Does the source of stress (poverty, neighborhood violence, pollution) also lead to asthma symptoms?

- Are stress and asthma just fellow travelers?
- Does maternal stress affect how mothers and professionals react to asthma (admission more likely at a given level of symptoms, for example)?
- Since antenatal and postpartum maternal stress are likely closely linked, it may be difficult to determine which is important.
- Does stress lead to Berkson's bias (above)?

The interaction between maternal atopy and wheeze was studied in 653 families.[78] Stress was defined as negative life events during pregnancy and in the first and second years postpartum. Mothers were asked about the presence of wheeze in the babies quarterly. Maternal stress was a risk factor for wheeze, but only in nonatopic mothers. This was taken forward in a second, more mechanistic study in 557 families.[79] Prenatal maternal stress was defined as any of financial hardship, difficult life circumstances, community violence, and poor neighborhood housing. Cord blood mononuclear cells were incubated with several stimuli of the innate and adaptive responses. There were greater interleukin (IL)-8 and tumour necrosis factor (TNF)-$\alpha$ responses to infection-based, and a higher IL-13 and reduced IFN-$\gamma$ to house dust mite (HDM) stimuli ($T_H2$ polarization), but there was no explanation of the detailed mechanisms. However, there is at least one possible way in which altered responses to infection may impact longer-term outcomes, namely via upper airway bacterial colonization. The first Copenhagen Prospective Studies on Asthma in Childhood (COPSAC) Study reported on 321 infants who had hypopharyngeal cultures performed at 1 month of age, which these were infants of atopic mothers.[80] Twenty-one percent colonized with one or more of *Staph aureus, Moraxella catarrhalis, Strep pneumonia, Haemophilus influenzae,* and when followed up, they had worse wheeze outcomes, both in terms of percentage with any wheeze, and percentage with persistent wheeze. However, it should be emphasized that maternal stress was not measured in the COPSAC study.

A further study reported conflicting interactions between atopy and maternal stress.[81] The investigators approached 989 women, of whom 488 (<50%) were actually studied. They used the Crisis in Family Systems-Revised (CRISYS-R) questionnaire (which has 11 domains that were summarized to account for stress in multiple domains). They performed prenatal environmental HDM sampling and measured cord blood immunoglobulin E (IgE). They reported that maternal stress was associated with higher cord blood IgE; confusingly, for atopic mothers, the strongest association was in the high HDM exposure group, whereas in the nonatopic mothers, the reverse was found, the strongest association being in the low HDM group. These findings are difficult to explain, although supportive of an association between maternal stress and atopic outcomes.

Even more intriguing was a study looking at early life events in the mother herself long before pregnancy.[82] The investigators defined the mother's SES in childhood, age up to 10 years, by whether she lived in a home owned by her family. They recorded potential pregnancy effects, including sociodemographics, exposure to violence or trauma, financial status, and exposure to allergens and traffic pollution. Postnatally, they recorded reported wheeze every 3 months. They reported that lower maternal SES was associated with higher cord blood IgE and more infant wheeze. They also reported direct effects, namely cumulative maternal adversity was independently associated with cord blood IgE; and indirect effects, operating through adult SES, cumulative stress, and pollution. They proposed a complex model integrating all these findings, but it has to be said that mechanistically there are no answers and the model must be said at this time to be hypothesis generating not definitive.

In summary, maternal stress is clearly *associated* with altered cytokine responses ($T_H2$ and innate immune responses to infection) in the baby. There is also a readout with increased reports of wheeze in the offspring, but the weaknesses of relying on parental reports of wheeze have been highlighted elsewhere.[83–86] The pathways are clearly complex and ill-understood, although the interactions between stress and atopy are important. However, we are a long way from proving causation, since so many factors cosegregate with stress.

## Long-Term Effects of Events During Delivery

Caesarean section delivery is *associated* with an increased risk of atopic disorders in the baby[87,88] probably mediated via an effect on the fetal microbiome.[89] Especially if at least one parent is allergic, children delivered by Caesarean section are more likely to have asthma at 8 years of age, and children of nonallergic parents are more likely to be sensitized.[90] Since there are no randomized controlled trials of Caesarean section delivery, it is not clear if the reported asthma prevalence changes are related to Caesarean delivery itself or to the reason Caesarean delivery was undertaken.

A further factor to be considered is changes in the way newborns (including term newborns) are resuscitated.[91] Many babies require a brief period of resuscitation immediately after birth and thereafter remain well and are not reevaluated. Resuscitation policies have become less aggressive, with intubation and hyperoxic gas mixtures given after a delay, and there is evidence in animals that this may be less damaging to the newborn lung.[92] The long-term sequelae of newborn resuscitation have not been considered outside the setting of prematurity, but the long-term effects of these changes are worth at least considering.

The Canadian CHILD (Canadian Healthy Infant Longitudinal Development national population-based birth cohort [www.canadianchildstudy.ca]) study has also reported on the interactions between mode of delivery, the use of intrapartum antibiotics, and subsequent breast-feeding on the fecal microbiome in infancy.[93,94] Intrapartum antibiotics for whatever indication (Group B streptococcal prophylaxis, prolonged rupture of membranes, and elective or emergency Caesarean section) led to alterations in the fecal microbiome at 3 months of age and these persisted in babies delivered by Caesarean section to a year of age, particularly if the Caesarean section was an emergency and the infant was not breast-fed. The development and importance of the early life microbiome is discussed in more detail below.

## Birth Weight and Gestational Age

The long-term consequences of extreme prematurity are considered later; here we discuss the effects of modest decrements in birth weight and gestational age, and some of which have hitherto been thought to be in the “normal” range. A meta-analysis has demonstrated that low birth weight of whatever underlying cause is associated with subsequent asthma across the life course.[95] There is a linear relationship between birth weight (adjusted for all known relevant maternal factors) and spirometry both at the peak in the early twenties and at age 45 to 50 years.[96] Tobacco smoking causes preterm delivery and importantly the risk is reduced by tobacco legislation[54]; it is obviously of the first importance to focus particularly on factors that are remediable, such as smoking and pollution, rather than those that are not, such as maternal atopy. Modest degrees of prematurity (up to 37 weeks gestation) are associated with impaired spirometry in the late teenage years[97] and increased prescription of asthma medications in childhood.[98–100] Low birth weight of itself is a risk factor for subsequent asthma.[101] There may be a differential effect of low birth weight in babies who are small (SGA), as opposed to appropriate (AGA), weight for gestation age; at age 20 to 22, spirometry was strongly predicted by birth weight in the SGA, but not the AGA, group.[102]

## Normal Postnatal Lung Growth

Most is known about airway growth and the Global Lung Initiative has provided the best all-age spirometry data. These show a steady rise in lung function from the preschool years to a plateau between ages 20 and 25 years and then a steady decline.[103] If these figures are back-extrapolated to birth cohort studies that have used either the rapid thoraco-abdominal compression technique (RTC) or the raised volume RTC (RVRTC), which is more closely relates to spirometry in children and adults, it is clear that there are three key issues that are needed to ensure lifelong airway health (Box 15.3)

**Box 15.3**

### Three Key Stages for Lung Health

- Normal lung function as shown by RVRTC/RTC at birth (genes and antenatal factors)

- Normal lung growth in the first two decades of life (genes, postnatal and antenatal factors)
- Normal rate of decline, from the fourth decade of life (genes, antenatal and postnatal factors; minimal contribution from adult life effects)

*RTC,* Rapid thoraco-abdominal compression technique; *RVRTC,* raised volume rapid thoraco-abdominal squeeze technique.

We have learned important lessons from birth cohort studies. There is no study that has extended over the entire life course, and so we rely on a series of overlapping cohorts,[104–107] reviewed in.[108] Although there are some discrepancies, the general message is that lung function at age 4 to 6 years is determined by lung function and AHR soon after birth, and thereafter tracks; hence decrements at age 4 to 6 are reflected in adult lung function, at least to age 50. There may be further deterioration over the life course, but no improvements. This has obvious implications for adult disease.

Understanding AHR and its long-term consequences requires a developmental perspective. Three groups have measured neonatal AHR and all showed significant relationships with long-term respiratory outcomes, albeit slightly different.[38–41] COPSAC[41] showed that 40% of airway obstruction at age 7 was determined antenatally and 60% postnatally and that AHR in the newborn period was the strongest predictor of asthma at age 7. Neonatal AHR is clearly not related to airway inflammation[42] or previous infection, and must be determined by anatomical factors; thus, in small airways, resistance increases more for a given proportionate radius change. Although AHR and lung function at birth are said to be independent risk factors for childhood lung function, abnormal anatomy is likely to be the root cause of both. Finally, a study of AHR from birth to adult life showed that the relationship in adulthood between AHR and asthma was established before 6 years of age.[109]

There is much less known regarding developmental changes in lung volumes. They probably increase through childhood, with at least one study suggesting a phase of accelerated growth during puberty,[110] and more marked in boys than girls, reflecting changes in the dimensions of the thoracic cavity.

Alveolar development is a controversial subject. Conventionally, this has been described as being a largely postnatal phenomenon with a rapid phase in the first 2 years of life, while there is some neo-alveolarization until about age 8 years, at which point, alveoli increase only in size and not number. This has been challenged by some controversial studies in which hyperpolarized Helium ($He^3$) has been used to infer alveolar size from observation of path lengths after inhalation.[111,112] These studies have suggested that neo-alveolarization continues throughout somatic growth, which is supported by direct morphometric measurements in primates.[113] If this is the case, the implications are two-fold; first, there is greater scope for recovery from adverse neonatal events than we thought; and second, the period of vulnerability of the growing alveoli extends further than we previously considered. These are both particularly important in the context of preterm delivery and adverse environmental exposures.

## Adverse Impacts on Lung Growth and Relationship to Disease Outcomes

As with neonatal adverse influences, the postnatal interactions between adverse effects and their consequences are complex. Included in this are the ways whereby an adverse influence causes long-term respiratory morbidity by leading to obesity, which obviously of itself causes substantial respiratory morbidity. Another example is wheezing and asthma, which are associated with adverse long-term effects, but have magnified effects by acute exacerbations of wheeze or “lung attacks” (below).

### Effects of Nutrition on the Life Course of Lung Development

The single most easily modifiable trait that may impact on long-term outcomes is breast-feeding. The general health merits of breast-feeding are too well known to recapitulate here. Whether breast-feeding protects against asthma and wheeze is controversial; a meta-analysis showed benefit in the first 2 years of life, with diminishing effects thereafter[114]; however, a recent birth cohort study did not confirm any protective effect at age 7 years.[115] Breast-feeding is also associated with a reduced risk of snoring and sleep-disordered breathing,[116] and likely, but not certainly, protects against obesity. Early and rapid weight gain may be associated with poorer lung growth in addition to the effects of low birth weight and SGA.[117] However, paradoxically, greater weight gain (but almost certainly not obesity) in later childhood may be associated with better spirometry.[118] The multiple respiratory adverse effects of childhood obesity including a number of phenotypes of wheeze, deconditioning, and obstructive sleep apnea are well known. There is mounting evidence that the origins of later obesity are antenatal and in the first 2 years of life. In a systematic review, 282 publications were identified, from which high maternal prepregnancy body mass index, prenatal tobacco exposure, excessive maternal weight gain in pregnancy, high birth weight, and greater weight gain were implicated as risk factors for childhood obesity.[119] There was less strong evidence (fewer studies) implicating gestational diabetes, child care attendance, poor maternal-infant bonding, low SES, reduction in infant sleep time, inappropriate formula feeding, introduction of solid foods before 4 months of age, and infant antibiotic exposure. Clearly many of these risk factors are interlinked, such as low SES, smoking, and low rates of breast-feeding.

## Passive and Active Exposure to Tobacco Smoke

The effects of passive smoking were described in a series of meta-analyses,[120–126] which have been recently updated.[43] Passive smoke exposure is associated with an increased risk of sudden infant death syndrome, more and more severe childhood upper and lower respiratory infections, and more childhood wheeze. Finally, maternal smoking and the child taking up smoking (which is more likely if the parents smoke) have additive effects on the child's lung function.[127]

## Environmental Pollution

Globally, the most significant antenatal exposure is indoor exposure to biomass fuels. In a study from Guatemala,[128] a subset of children whose families had been randomized to receive a chimney stove to reduce indoor pollution either at birth or at 18 months of age underwent spirometry at around 5 years of age. Later stove introduction was associated with a statistically significant reduction in peak flow growth and a large but not statistically significant decrement in $FEV_1$.

There is a large amount of literature on the adverse respiratory effects of ambient pollution. Lung growth over time is adversely affected by pollution,[129,130] meaning that the normal plateau of lung development will not be reached, putting the child at risk of later COPD. Furthermore, pollution interacts with respiratory infection to increase the prevalence and worsen attacks of preschool wheeze and asthma[131,132] with the adverse long-term results described below. Encouragingly, legislation to reduce air pollution is also temporally associated with improved lung growth in children, identifying outdoor as well as indoor pollution as something that can and should be dealt with to preserve long-term lung health.[133]

## Asthma, Atopy, and Acute Attacks of Wheeze

Three factors reflecting long-term consequences of childhood asthma and wheeze emerge from the literature: (1) the importance of different temporal patterns of wheeze[134,135]; (2) the significance of different patterns of atopic sensitization[136]; and (3) the crucial importance of attacks of wheeze, or better "lung attacks."[137,138] These last have been the subject of attention in other contexts (as follows) including CF[139–141] and primary ciliary dyskinesia.[142] It has been suggested that these are so important that the rather feeble word "exacerbation," implying a mere temporary and reversible inconvenience, should be replaced by the more forceful "lung attack" to reflect the long-term adverse effects of these episodes in many airway diseases.[143,144]

In terms of wheeze patterns, the birth cohort studies have confirmed the shrewd observations of our forebears that all wheeze is not the same, and 4 to 6 patterns or phenotypes can be discerned,[145–147] which are broadly reproducible across the cohorts, and associated with particular gene expression patterns.[148] Broadly, there are early wheezing periods in the first 0 to 4 years of life and persistent and late onset wheeze phenotypes leading to symptoms into mid-childhood. The cohorts with more sophisticated epidemiological classifications have yet to reach late adulthood, so the long-term consequences can only be inferred. An alternative, and more clinically useful, time-honored classification, recently endorsed by the European Respiratory Society, is into "wheezy bronchitis"/episodic viral wheeze (symptoms only during viral upper respiratory tract infections) and asthma/multiple trigger wheeze, in which additionally there are symptoms between infections, with typical asthma triggers such as exercise and allergen exposure.[134,135] The Aberdeen cohort, which used just this classification, has been followed into the seventh decade and showed that both groups were associated with COPD, but neither were associated with an accelerated decline in spirometry[10]; hence, failure of normal lung growth in childhood was the cause of COPD in adult life. In this context, it is worrying that one-third of children with relatively mild asthma in the CAMP study had impaired growth in spirometry irrespective of whether they were prescribed ICS.[11,149] This is one more indication of the disconnect between airway inflammation and airway remodeling, which was presumably the cause of impaired growth.

We have also come to realize that all atopies are not equal, and approaches such as the quantification of atopy and determining the temporal patterns of sensitization lead to delineation of subgroups of atopy of different significance. The Manchester cohort used a machine learning approach to define patterns of atopy, and this approach identified early multiple atopic sensitization and persistent wheeze as being the only combination of wheeze and atopic phenotypes that predicted progressive airflow obstruction measured by specific airway resistance.[136,137] Additionally, attacks of wheeze worsened the progression of airflow obstruction.

Lung attacks have been specified as important in the evolution of lung function in two contexts: the first is the Manchester birth cohort study[137]; and the second is in a *post hoc* analysis of the Inhaled Steroid Treatment as Regular Therapy in Early Asthma (START) trial[138] in which asthma lung attacks were shown to be associated with a long-term effect on airway obstruction; in this case, the effect was abrogated by treatment with ICS.

Finally, the Melbourne study has shown that people with asthma that remits and normal subjects have the same spirometry in the sixth decade of life, whereas asthma that does not remit (even if not severe at recruitment) is associated with decrements in lung function across the life course.[150] Risk factors identified for persistence were severe childhood asthma, female gender, and childhood hay fever.

## Stress and Its Outcomes

A number of manuscripts link childhood psychological stress with asthma attacks; but as in other areas, associations are described, and there are no intervention trials to prove that psychological intervention is beneficial. In the most significant prospective longitudinal follow-up study, 113 children were approached and 90 participated.[151] They filled in the Psychological Assessment of Childhood Experiences (PACE) questionnaire at baseline, 9, and 18 months and undertook home peak flow monitoring. Acute, severe stresses were defined as a death or divorce in the family, while chronic stresses were chronic physical or mental illness in family, substance abuse, family discord, school-related stress (bullying), and poor living conditions. They found that female gender, higher baseline severity, frequent previous attacks, and (unsurprisingly) the autumn to winter season were all associated with more attacks. Although this is expected, these positive controls add value to the study by demonstrating adequate power to show real associations. They reported that social class and chronic stress were not associated with acute attacks. Severe acute events, with or without high chronic stress, however, did increase the risk of new asthma attacks. There were quite complex time-relationships between stress and asthma attacks. If there was no background chronic stress, there was a time lag of around 2 weeks before the increased risk of acute attacks, which was manifested in the subsequent 4 weeks.[152] If the child suffered from acute on chronic stress, there was an almost immediate increased risk of asthma attacks. In other work, detailed analysis revealed a biphasic risk pattern with early and late periods of vulnerability.

The effects of positive life events have also been studied.[153] “Acute” positive events were defined as receiving valued presents, joining clubs (new activities and friends), and winning prizes.

"Long-term" positive events included being a member of a sports team and having a hobby. The group had low to medium chronic stress levels, but not high chronic stress. They found that positives could reverse the risk of an acute stressful event, but the presence or absence of long-term positives did not affect attack risk.

Finally, a horrifying paper from Brazil studied the effects of violence on asthma attacks.[154] A total of 1232 parents/guardians were surveyed, and, appallingly, more than three-quarters had been exposed to violence. Children exposed to violence were more likely to report asthma (International Study of Asthma and Allergies in Childhood [ISAAC]; 28.4% vs. 16.4%), and if violence was maximal, the odds ratio for asthma was 1.94, with 95% confidence intervals of 1.12 to 3.36. Of course, one cannot exclude that what was being reported by the children was hyperventilation or panic attacks, triggered in part by traumatic events.

Another approach is to look at new cases (incident) of asthma rather than exacerbations of a preexisting disease. One group conducted a postal survey of 16,681 males and females, aged 20 to 54, to determine the presence of stressful life events and determined the onset of asthma from national registries.[155] There were 192 cases of incident asthma, which were associated with acute stress; the worst were illness of family member, marital problems, divorce or separation, and conflict with a supervisor. Again, whether they were reporting true asthma or dysfunctional breathing could not be determined.

## Antibiotics?

This literature clearly shows the importance of not confounding causation and association. Many papers show an association; a recent study in more than 900 babies followed to age 11 years obtained data on prescription of antibiotics, wheeze prevalence, and asthma attacks.[156] Peripheral blood mononuclear cell responses to rhinovirus and respiratory syncytial virus, and *H. influenzae* and *Streptococcus pneumoniae* were assessed at 11 years, and genotyping for polymorphisms at the 17q21 locus was performed. The expected association of wheeze and asthma with antibiotic prescription was noted, but the children who were prescribed antibiotics were in fact significantly different from those who were not both in terms of immunological responses to viruses but not bacteria and 17q21 polymorphisms. Hence, the association between wheeze and antibiotic prescription is likely related to confounding factors and not causative.

## Early Viral Infections

Acute viral infections are important causes of early respiratory morbidity due to bronchiolitis and wheeze, but whether viruses cause asthma to develop in an infant who would otherwise not go on to the disease or are a marker for an asthma propensity is controversial. It should be noted that these are not mutually exclusive. Cord blood studies (above) show that the host immune system may be programmed before birth such that the baby has a propensity to viral wheeze. Another study demonstrated impairment of respiratory function prior to the development of bronchiolitis, and this decrement tracked into mid-childhood.[157] Respiratory syncytial virus has been most studied; infection with this virus in infancy is universal, but whether severe infection causes asthma is controversial.[158,159] Recently, rhinovirus infection has been shown to be more strongly associated with subsequent asthma than respiratory syncytial virus, although association and causation are not the same.[29] Probably, allergic sensitization precedes viral wheezing,[160] and it is likely that sensitization rather than viral infections is important in pushing the trajectory of the child into school-age asthma, although this is by no means certain.

## Microbiome

The lower airway is not sterile as was once believed based on conventional culture techniques. Molecular techniques, which detect a hundred-fold more bacteria, have shown that the airway has abundant flora.[161] Furthermore, alteration in the normal lower airway flora may skew immune development,[162,163] and interactions between allergen and the microbiome influence the body's immune responses.[164,165] Early nasopharyngeal bacterial colonization of human infants is associated with altered early immune responses,[166] and a greater prevalence of subsequent wheezing[167] and worse respiratory infections.[168] It is likely that early upper airway colonization with pathogens is a sign of an underlying mucosal immune defect, but this is still unproven. By contrast, environmental bacterial and fungal diversity is associated with a reduced risk of asthma.[169] The long-term effects of an abnormal early microbiome on lung aging are currently unknown, but the influences on asthma risk mean that the early microbiome will at least have an indirect effect on outcomes.

## The Aging Lung

There are a large number of studies of lung aging, including population based and in those with established COPD. As discussed above, no single factor operative in adult life emerges as associated with accelerated decline in lung function; either no factors are identified, or they are not replicated. The Evaluation of COPD Longitudinally to Predict Surrogate Endpoints (ECLIPSE) study showed there was accelerated decline in current smokers, patients with a bronchodilator response, and patients with emphysema[6]; the Body Mass Index, Airflow Obstruction, Dyspnea and Exercise Capacity Index (BODE) study[7] by contrast reported higher rates of decline in those with a higher basal metabolic index and a higher starting $FEV_1$. A study in adults with severe asthma showed that an elevation in exhaled nitric oxide, especially in those with $FEV_1 \geq 80\%$, was predictive of accelerated decline in lung function.[170] The likely pathological basis of this is an abnormal airway inflammatory response, elevation of CD8 and CD4 T cells in baseline bronchial mucosal biopsies and CD8, CD3, and granzyme B at follow-up.[171]

## Lung Development: More Than Just Airways

Much less is known about alveolar as opposed to airway growth, and it is mostly in the context of prematurity and its treatment. Neonatal hyperoxia, systemic steroids, and nicotine all impair neoalveolarization via effects on secondary septation in animals.[172–174] Human $He^3$ data[175] suggest that maternal smoking in pregnancy, as well as affecting the airway, may increase alveolar size and reduce their numbers leading to premature “emphysema.” Since it is nicotine that is implicated in both processes, the safety of e-cigarettes is called into question.[176] There may be the alveolar equivalent of catch-up growth based on cross-sectional studies; there are no longitudinal neonatal data with extension into childhood and adult life. Carbon monoxide transfer ($DL_{CO}$) is a surrogate for the size of the alveolar-capillary membrane, and one group demonstrated that this was normal at rest and on exercise in adult life.[177] $He^3$ data in preterm survivors in adolescence showed that alveolar size was normal,[112] implying catch-up growth, but there were no measurements in the newborn period. Nitrogen washout can be used to partition gas mixing abnormalities into airway ($S_{cond}$) and alveolar ($S_{acin}$) components.[178,179] Preterm survivors in childhood had as expected an abnormal $S_{cond}$ compared with controls, but $S_{acin}$ was normal, implying alveolarization had normalized (but again, there were no neonatal data).[180] However, if in fact many alveoli had been completely destroyed, $S_{acin}$ would still be normal. However, taken together, there is suggestive evidence that alveolarization continues for longer and with more potential for catch-up growth than previously thought. Certainly, lungs apparently destroyed by necrotizing pneumonia usually recover completely,[181] so there is certainly potential for catch-up. Intriguingly, being reared in hypoxic conditions at altitude appears to stimulate alveolarization but has no effect on airway function[182]; this raises the hitherto unexplored question as to whether keeping preterm survivors very well oxygenated is as beneficial as we currently think.

## Summary: What Have We Learned About the Importance of Antenatal and Childhood Factors?

We have summarized factors across the developmental spectrum that clearly either lead to either or both of impaired lung function at birth and impaired lung growth in childhood leading to a failure to reach the normal adult plateau. There are clearly important genetic effects and gene by environment interactions discussed elsewhere in this book (see Chapters 3 and 4).

It is very clear that asthma and many if not most childhood wheezing syndromes, including atopic asthma, are not mere childhood inconveniences to be outgrown but have long-term consequences in terms of premature airflow obstruction and thus early onset of respiratory disability. The exact importance of multiple factors operative in an individual may not be possible to dissect, but the importance of a focus on antenatal and early childhood factors is indisputable. The combined effect of these adverse influences and their childhood consequences is to lead to an increased risk of adult COPD (below). However, what is also clear is that the rate of lung aging must be largely dependent on genetic and childhood factors. The inescapable conclusion is that if adult COPD is to be prevented, then efforts to do this must be focused in childhood.

## The End-Stage—Chronic Obstructive Pulmonary Disease

Damage to an airway can only manifest by premature onset of airway obstruction, just as the end stage of insults to the kidney is an elevation in serum creatinine. Thus, to define a disease (COPD) by a fixed ratio ($FEV_1/FVC$) of <70% is as imprecise as calling a raised serum creatinine a disease and is almost incomprehensible to most pediatricians. Furthermore, as age increases, more and more people have a ratio in the “COPD” range, and in young children, $FEV_1/FVC$ of 75% is very abnormal[183]; so using a fixed ratio across the developmental spectrum is akin to defining short stature as being 120 cm tall without knowing the age of the patient! The best life course study from Melbourne has a number of important lessons.[150] First, the risk of adult “COPD” is 30-fold greater in those with severe asthma, a signal far outweighing that of smoking. Second, those with COPD fail to reach the normal spirometric plateau but undergo lung aging at the same rate. Finally, those given an adult diagnosis of COPD were those with the most abnormal spirometry at age 10 years. This paper should surely kill the concept of a disease diagnosed by a ratio stone dead (but probably it will not!); premature airflow obstruction does not happen when an arbitrary fixed threshold is crossed but happens across the life-course. Therefore, either adult “COPD” therapeutic strategies such as ICS, antimuscarinics, and long-acting β-2 agonists should be applied across the life course irrespective of the etiology of the airflow obstruction rather than waiting for a fixed and arbitrary line to be crossed; or more logically, dissect airway disease into components such as inflammation, infection, and fixed and variable obstruction, as discussed in Chapter 46, and deploy treatment against such treatable traits as are present.

# Long-Term Consequences of Specific Diseases

## Prematurity, Including Early-Term Delivery

Despite there being a large amount of literature on the long-term consequences of prematurity, many adult physicians are not aware of the problem and do not even make early life events part of the clinical history.[184] The literature can only briefly be summarized here. The possible reasons for adverse effects of prematurity are complex (Box 15.4).

**Box 15.4**

### Adverse Factors Interacting With Prematurity

- The effects of prematurity itself
- The effects of treatment of prematurity (especially supplemental oxygen, barotrauma and systemic corticosteroids; Caesarean section delivery
- The effects of the underlying cause of premature delivery, such as maternal smoking or hypertension
- The effects of low birth weight independent of prematurity (including small vs. appropriate for gestational age)

- Genetic effects: 258 genes have been associated with BPD[185]
- The effect of programming by events at a critical time period (DOHAD)
- The indirect effect of premature delivery on the baby, operating through the mother, such as maternal stress

The resuscitation and treatment strategies used for premature babies have changed and are likely to develop further. Modern ventilator strategies (high rate, low pressures), for example, may lead to very different sequelae compared to older methods (lower rate, higher pressures). Long-term survivors have tended to have airway disease and obstruction, whereas the smaller, more preterm survivors of neonatal intensive care in the 21st century have alveolar hypoplasia.

It is also important to note that even babies delivered at early term (37 to 38 weeks gestation) have respiratory morbidity in mid-childhood, as discussed above. The implication is that early delivery *per se* is deleterious, and so improvements in neonatal intensive care will not take away the problems of prematurity; consequently, there is a much larger pool of at-risk children than may have been thought.

Summarizing the literature, survivors of preterm delivery have increased respiratory symptoms and morbidity going into adult life; they have fixed and variable airflow obstruction, but without evidence of eosinophilic airway inflammation; and they have alveolar hypoplasia and structural parenchymal damage. Additionally, they may have impaired exercise performance, abnormal control of breathing, and pulmonary hypertension. Most survivors of preterm delivery have, however, been lost to medical follow-up and are living active lives in the community. It is likely but not proven that many of them will be being treated inappropriately for “asthma” with ICS because of symptoms and abnormal physiology, again emphasizing the need to deconstruct airway disease into its components.

There have been no really long-term studies following these survivors into late adult life, and in any case, such studies are likely not relevant to modern survivors. It is likely, however, that they will not reach a normal plateau of spirometry, and thus will be at high risk of "COPD." There is no information about whether there is an accelerated rate of decline in this group. It will be really important that these people have their airway disease evaluated critically; it is hard to believe that the survivor of prematurity who has never had airway eosinophilia should be treated the same way as a lifelong smoker or a severely atopic asthmatic just because all three have an $FEV_1$/FVC ratio <70%.

## Implications for Specific Diseases Such as Cystic Fibrosis and Primary Ciliary Dyskinesia

The general focus on these inflammatory airways diseases is to treat disease specific manifestations, especially airway infection and inflammation, the latter of which may be (but is not inevitably) damaging in its own right; and of course this is very important. However, there is no evidence or biological plausibility that because the child has one of these diseases they are exempt from the early adverse events (e.g., maternal smoking) on the airway and alveoli as discussed above. The inevitable conclusion is that, no matter how excellently (say) a CF clinic delivers multidisciplinary care, outcomes will be less good if general childhood lung health is neglected. This is one powerful argument for newborn screening for CF, although even this will preclude addressing antenatal factors. It is more worrying for conditions such as primary ciliary dyskinesia that are diagnosed symptomatically, often very late. This highlights the importance of diagnostic alertness to, for example, unexplained neonatal respiratory distress, so early intervention is possible.

The other important implication is the importance of lung attacks as more than just a temporary inconvenience. So in patients with CF, and in one small study of primary ciliary dyskinesia, around 30% of patients did not recover lung function despite treatment with intravenous antibiotics.[140] CF lung attacks have also been shown to be associated with a greater subsequent rate of decline in spirometry and a greater risk of death or lung transplantation at follow-up.

## Summary and Conclusions

This chapter has discussed the transgenerational, antenatal and early childhood factors that affect lung development across the life course. The consequences of these adverse influences may be direct or secondary to an intermediate disease state such as prematurity and obesity. Many of these adverse effects cannot be remedied; we cannot stop atopic women bearing children, for example! There are two important take-home messages. The first is that we must identify and focus on what is preventable. This means legislation to protect vulnerable lungs against tobacco and nicotine (cigarettes and e-cigarettes), and traffic pollution; the institution of affordable and practical measures to minimize or eliminate exposure to biomass fuel; and being sure that due weight is given to the longer-term consequences of Caesarean section by women and obstetricians when planning delivery. The second is to convince the community, especially adult thoracic physicians, to see that many lung diseases would disappear if our vulnerable fetuses, babies, and infants were better protected from the consequences of adult behavior.

# Drug Administration by Inhalation in Children

*Angela Mary Fonceca PhD, William Graham Fox Ditcham PhD, Mark L. Everard MD, Sunalene Devadason PhD*

Aerosol therapy is the cornerstone of treatment for many respiratory disorders in children. For those with asthma, the use of inhaled β-agonists and corticosteroids has formed the basis of optimal therapy for many decades, while inhaled antibiotics are increasingly being used to treat patients with cystic fibrosis and other forms of bacterial bronchitis (with or without bronchiectasis). The inhaled route has the advantage of more rapid onset of action for β-agonists; reduced systemic exposure for a given therapeutic effect for a range of drugs including corticosteroids, β-agonists, and antibiotics, and it also permits the use of certain drugs such as tobramycin, which are not readily absorbed by the enteral route. The improved therapeutic index of inhaled therapy as compared with oral therapy for the treatment of pulmonary disease is of course relative and systemic side effects do occur with high doses. For example, significant adrenal suppression can result from the use of high doses of inhaled corticosteroids (ICS), this being more likely when doses in excess of licensed doses are used.

While a great deal of research has gone into the development of devices that enable more efficient delivery of drugs to the lung, the commercial inhalers that are most widely used, particularly for children, are largely based on technologies that are more than 60 years old. These systems include pressurized metered dose inhalers (pMDIs), which may be used with or without an attached spacer or holding chamber. Few patients can use pMDIs optimally without spacers or holding chambers, which may be valved or unvalved. Spacers have the advantage of removing much of the upper airways' deposition of drug, which helps reduce local side effects. Thus, spacers should be used by anyone prescribed an ICS in a pMDI. Dry powder inhalers (DPIs) are currently dependent on a forceful inhalation to aerosolize the drug and hence are not suitable for preschool children. However, they do represent a valuable class of delivery system both for the treatment of asthma and, increasingly, for the delivery of antibiotics. Traditional jet nebulizers, whose basic design goes back many decades, are being used less frequently while devices such as vibrating mesh nebulizers, which are quiet and provide more rapid delivery of drug, are being used increasingly for antibiotic therapy.

## Advantages and Disadvantages of Aerosols for Drug Delivery

Inhaled aerosolized drugs enable more direct access to the respiratory and cardiovascular systems (Table 16.1), which both include lung perivascular tissues. Aerosol drug delivery is most commonly used in children for the treatment of respiratory conditions such as asthma, cystic fibrosis, croup, and bronchopulmonary dysplasia. An inhaled entry route provides relatively unhindered access to actively exchanging capillary beds in the lungs. This ensures more rapid onset of drug action within the target organ compared with other administration methods such as oral (swallowed solid or liquid doses) and subcutaneous or intramuscular injection routes. Therefore a lower dose is needed for an equivalent effect[1] and aerosol delivery has the advantage of reducing systemic side effects.

### Table 16.1

**Advantages and Disadvantages of Drug Administration by Inhalation Compared With Oral or Parenteral Administration**

| Advantages | Disadvantages |
|---|---|
| Improved therapeutic index compared with systemic administration (reduced incidence of systemic side effects for a given therapeutic effect) | The more portable metered dose devices (pressurized metered dose inhalers used alone, and dry powder inhalers) require specific inhalation techniques for optimal delivery |
| More rapid onset of action for bronchodilators | Correct use of current portable devices is not intuitive; repeated training in optimal use is often essential |
| Ability to administer drugs to the lungs that are not effective via the oral route due to poor gastrointestinal absorption or hepatic first pass elimination | Drug delivery is impaired in diseased regions of the lungs resulting in more central and heterogeneous distribution as lung disease progresses |

Devices used for aerosol drug delivery vary in design, which can be tailored for application or dose. However, instructions for use and optimal inhalation techniques vary greatly depending on device type, which can lead to confusion and misuse if patients are prescribed multiple devices for different drugs. Hence, to achieve optimal benefits, instructions for using a device are best achieved when given through personal professional guidance. Consistency of dosing can be an issue as this is affected by many factors including tissue and systemic absorption and airway obstruction as well as training and ability of the patient to perform the required inhalation technique. In addition, the patient's cognitive ability to use the device and anatomical factors specific to the patient's age or disease condition may affect the efficacy of drug delivery.

A good understanding of the principles that determine aerosol particle deposition within the lungs enables health professionals to assess the best drug-device “fit” for patients of different ages and disease conditions.

There is a wide range of types of aerosol delivery systems and formulations currently in use or in development; the focus of this chapter will be on aerosol delivery systems and therapeutic applications currently in use in children.

## What Is a Therapeutic Aerosol?

Aerosols are considered to be biphasic as they contain a gaseous and a particulate phase, which in practice equates to a gas in which solid and/or liquid particles are suspended.[2] The "gas" in which the aerosol is carried may be independently generated as part of the device itself (e.g., nebulizers using ambient air, medical air, or oxygen; pMDIs using hydrofluoroalkane [HFA] propellants). Alternatively, devices may require the patient's inspiratory air flow to disperse and "pull" the aerosol into the lungs (e.g., most DPIs currently used). The particulate phase consists of the therapeutic agent, generally in combination with additive compounds. Solid aerosols may consist purely of the therapeutic agent (e.g., Turbuhaler) or may contain a carrier (e.g., Accuhaler). Liquid aerosols may be solutions or suspensions; in either case, the solubility of the drug (whether in saline or propellant) will affect the aerosol characteristics. In addition, for solutions, the drug concentration and viscosity may be an important factor. The aerosol generation method of the device and the drug formulation in combination will affect the type of aerosol created and the efficiency with which the aerosol deposits in the lungs.

## Principles of Aerosol Delivery

In general, the higher the proportion of drug that can bypass the upper airways and deposit in the lung, the greater the therapeutic response obtained from a given label or nominal dose. Some factors that affect this therapeutic efficacy are listed in Table 16.2; of these, the particle size of the aerosol and the velocity at which it is generated and inhaled are two key determinants.

**Table 16.2**

**Determinants of Aerosol Deposition**

| Device and Formulation-Related Factors | Patient-Related Factors |
|---|---|
| Particle size | Age |
| Particle velocity | Inspiratory flow rate |
| Hygroscopic properties | Breathing pattern (inspiratory volume, rate) |

Mathematical modeling and deposition studies have shown particles with a mass median aerosol diameter (MMAD) of greater than 5–10 μm are likely to be removed in the upper airways (by way of comparison a red blood cell has a diameter of ~7 μm). The proportion of particles within this range penetrating into the lower airways is in large part dependent on the inspiratory flow. The slower the inspiratory flow the greater chance particles have to follow the inspiratory flow rather than impact in the upper airways. More particles will reach the lower airways if inhalation is via the mouth rather than the nose. Particles less than 1 μm are generally exhaled as their inertia and settling velocities are very low, though particles in the nano-micron range do deposit with increasing efficiency by bypassing the upper airways and depositing through Brownian motion. (A 1 μm particle carries 1000 less drug mass than a 10 μm particle.) Within the so call "respirable range" (roughly 1–7 μm) the pattern of distribution varies with finer aerosols tending to deposit more peripherally and the coarser ones tending to deposit in the conducting airways.[3–5] The pattern of deposition in an individual subject is influenced by particle size (affecting the likelihood of depositing through impaction or sedimentation, inspiratory flow (affecting the likelihood of impaction in upper and central airways) breath holding (influencing the deposition by sedimentation distally), as well as airway geometry, which can be influenced by age, natural variation, and disease.

Currently available commercial inhalers are primarily designed to generate heterodisperse or polydisperse aerosols (Fig. 16.1), with a mixture of particle sizes within a given "respirable" range, to ensure deposition in the different regions of the lung and, in part, to compensation for variability in patient use of the devices. Regional differences in drug deposition within the lung affect local responses and thereby treatment efficacy.[6,7]

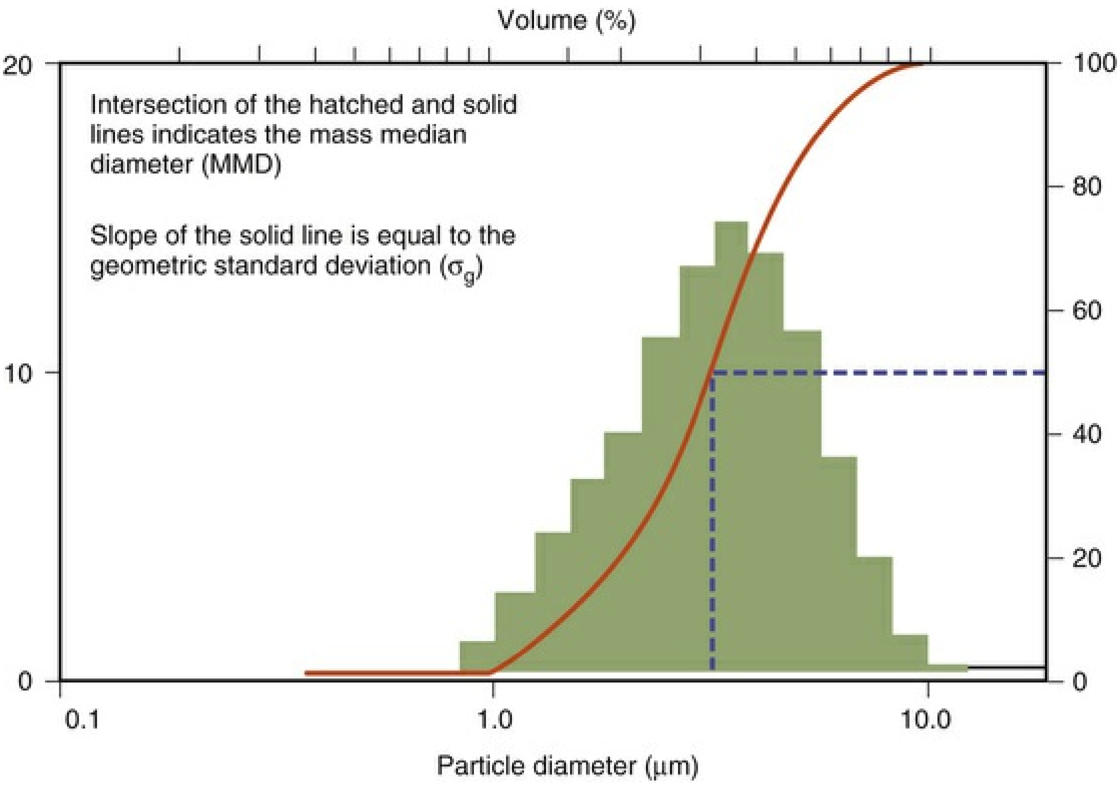

**FIG. 16.1** The particle size distribution of a medical aerosol generator that has been measured by laser diffraction. Each bar to the histogram represents a size band of particles (the height of the bar represents the percentage of the sample within that band). The scale on the left is used to read the histogram; the scale on the right is used to read the cumulative plot represented by the solid line going through the histogram. The particle size that corresponds to 50% on the cumulative curve is the MMD—in this case 3.3 μm. The slope of the line at the 50% point corresponds to the geometric standard deviation.

The most important consideration with aerosolized drugs is to maximize drug deposition in the required areas of the respiratory tract. Three main factors govern this: inertial impaction, gravitational sedimentation, and diffusion. In addition, the electrostatic charge on both the aerosol and the respiratory mucosa may affect drug deposition.[8–10]

Drug formulations for aerosol therapy consist of either aqueous solutions or suspensions. Solutions are a mixture of two or more components forming a homogenous molecular dispersion in a single-phase system. Suspensions consist of a dispersed system where insoluble solid particles are dispersed in a liquid medium.[11,12] Colloidal suspensions are made up of solid particles less than 1 µm in diameter, whereas coarse suspensions contain solid particles greater than 1 µm in diameter. Wetting agents are usually required for the dispersion of solid particles in suspension and generally consist of surfactants, which may make up 0.05%–0.5% of the drug suspension.[11,12]

# Physical Principles Affecting Aerosol Delivery and Deposition

## Particle Size

There are many factors that can affect the site and amount of aerosolized drug depositing in a patient's airways (see Table 16.2); the aerosolized particle size is one of the key determinants.[13] Particles less than 3 µm will deposit in the lower and smaller airways, whereas particles greater than 5 µm generally deposit in the oropharynx or upper airways.[14] Therefore minimizing the particle size of aerosolized drugs is essential for targeted deposition in the smaller airways. Due to the proportional cubic increase in volume of drug that can be carried with unit increase in the diameter of the particles, larger particles carry a much greater volume of drug. However, aerosols that contain a large proportion of particles greater than 15 µm in diameter will deliver most of the drug available for inhalation to the oropharynx. This results in little therapeutic effect and increased systemic exposure. Measurement of particle size is complicated by variability in the shape of aerosolized droplets, which may be irregular rather than strictly spherical. For this reason, particles of different shapes that behave in a similar manner (aerodynamically) are grouped together and visualized as spherical droplets with a common diameter, known as the aerodynamic diameter and geometric standard deviation (GSD). This is defined as the diameter of a sphere of unit density with the same terminal sedimentation velocity in air as the particle or droplet in question,[8] and is usually determined by the mass of the droplet. Most forms of aerosol therapy generate droplets of varying sizes known as polydisperse aerosol droplets, as opposed to monodisperse particles, which are characterized by uniformly sized particles of the same aerodynamic diameter. Polydisperse aerosols are further characterized by half of the aerosol mass having an aerodynamic diameter below the mass median aerodynamic diameter (MMAD), and half with diameters greater than the MMAD.[14] Overall, this means lung deposition for a highly polydisperse aerosol with an MMAD of 3 μm would be much lower than that for a monodisperse aerosol of the same diameter, whereas the reverse would be the case if the MMAD was greater than 5 μm.[15]

Optimizing the delivery of inhaled aerosols to patient populations is most important when drugs such as corticosteroids are being administered, especially in the pediatric age group. Ideally, drug delivery to the airways should be maximized, with minimal oropharyngeal and gastric deposition.

## Inertial Impaction

The way in which a particle travels in an airstream depends on momentum, which is determined by mass and velocity. High velocity ensures continued movement in a particular direction due to inertia despite obstacles or bends. However, these may cause the direction of air flow to change as when particles approach a surface such as the back of the throat or a bifurcation of the airways. Importantly, inhaled particles may not follow the direction of air flow, and instead may impact on the surface. Therefore particles with a higher momentum, such as larger particles or those with a higher velocity are more likely to impact in the oropharynx or the larger airways. Hence inertial impaction has a greater effect on larger particles (>3 μm),[10] and in areas where the velocity of inhaled particles is greatest; such as the oropharynx and upper airways.

## Gravitational Sedimentation

All particles will settle under gravity. Particles will accelerate to a steady terminal velocity when gravitational force is balanced by the resistance of air through which it is traveling, which is aided by breath holding.

Larger particles become filtered out by the upper airways and, as the velocity of these decreases, impaction is most likely to occur in the oropharynx, meaning particles greater than 15 μm are unlikely to enter the trachea.[15] Even for particles less than 15 μm, further deposition of the larger particles will occur at airway bifurcations.[16,17]

Particles less than 3 μm are unlikely to be affected by inertial impaction in the upper airways; therefore sedimentation due to gravity is the most important mechanism for deposition of these particles in the smaller airways. Within the less than 3 μm size range, the effect of sedimentation is greatest on the larger particles (>0.5 μm)[16,17] that have escaped deposition due to initial inertial impaction. Breath holding after inhalation of the aerosolized particles helps deposition in the airways due to sedimentation.[16,17] The rate of deposition though sedimentation reduces exponentially over time and as a generalization there is very little benefit to be gained from breath holds of greater than 10 seconds.

## Brownian Motion/Diffusion

Particles less than 0.5 μm are small enough to be perturbed by surrounding gas molecules. This bombardment (impaction with gas particles) can interrupt intended particle routes, which will move particles towards the surface of the respiratory tract, with the observed diffusivity being inversely proportional to the diameter of the particle.[8] For particles of 0.1–1 μm, deposition by sedimentation and diffusion is very slow but below this size (which includes a number of constituents of tobacco smoke) the efficiency of deposition through the effects of Brownian motion increases significantly, which is one of the reasons there are significant concerns regarding the increasing use of nanoparticles in manufacturing processes.[13]

## Electrostatic Attraction

Deposition may occur due to attraction between charged particles in the inhaled aerosol and an induced charge on the mucosa of the respiratory tract.[8] The extent to which this factor affects drug delivery and deposition has not been investigated in detail. The drug and other components of the formulation, device materials, and the generation of the aerosol from the device itself, can all affect the electrostatic charge of an emitted aerosol particle.

## Patient-Related Variables

Quite apart from the device and drug formulation related factors, patient related variables can markedly change the effective dose of aerosolized drug received by patients (see Table 16.2). These factors include anatomical and physiological variation between subjects as well as disease severity and distribution. However, the most important patient variable is their ability to use the device, both effectively and consistently, which is influenced in part by the quality of training provided.

As noted above, airway obstruction due to structural disease as in progressive bronchiectasis, bronchoconstriction as in asthma, or intraluminal mucus all contribute to more central deposition with hot spots in regions of flow limitation and distal areas of little or no drug delivery. For asthma, this is of relatively little consequence as the ICS lead to progressive improvement and improved homogeneity of deposition while β-agonists given in the face of diffuse constriction when the patient is symptomatic are probably redistributed to more peripheral regions of the lungs via the bronchial circulation. In progressive disease such as CF, the effectiveness of inhaled therapy is increasingly compromised as progressively less drug reaches the more diseased areas.

### Age

In some respects, the greatest challenges for using inhaled therapy result from cognitive and physical limitations at each end of the life course. For children, the period from birth to primary school is one of great change in physical and cognitive ability, which impacts their ability to use inhalers initially designed for use by adults. Conventional jet nebulizers with constant output can be used with standard tidal breathing at any age and can be used by infants and toddlers but they are relatively expensive, time consuming, inefficient, and often poorly tolerated by very young children (due to the noise and need to have a closely fitting mask). A holding chamber with a facemask can very effectively deliver drug to the lungs proving the infant/young child is not upset and will tolerate a closely fitting mask. Crying or screaming results in little or no drug reaching the lungs due to impaction in the upper airways, while if the mask is not closely fitting the patient inhales entrained air mainly rather than aerosol.

By their third birthday, most subjects are able to learn the "panting" technique with a mouthpiece, in which they take repeated inspiratory and expiratory breaths through their mouth when inhaling from a holding chamber. By 5–7 years of age, most will be able to master the optimal inhalation technique from a holding chamber with a slow inspiratory breath over 4–5 seconds followed by a 10-second breath hold or the rapid forceful inhalation required to optimally aerosolize drug from DPIs.

In terms of drug delivered, the absolute dose delivered to the lungs tends to increase over early life. For nebulized therapy, drug delivery probably reaches a maximal in the early preschool years as the inspiratory flow exceeds the flow of the nebulizer and the increased tidal volume consists of entrained air. However, drug delivery on a weight corrected basis is likely to be influenced by the device. The absolute dose delivered from a DPI with a reasonably steep dose to lung flow dependency curve may continue to increase into the teen years. However, the dose delivered per kilogram may be relatively constant for DPIs that are less flow dependent. The absolute dose delivered from a pMDI holding chamber combination may be fairly constant across age but the dose per kilogram will fall from the primary school ages as the child grows.

## Regimen and Device Compliance

Compliance with an optimal treatment regimen is commonly poor in all therapeutic areas resulting in suboptimal health outcomes. That is patients frequently miss multiple doses for a variety of reasons. The situation with inhaled therapy is compounded by the need to use prescribed inhalation techniques with many studies indicating that the majority of patients, physicians, and pharmacists are unable to use devices optimally. Hence, for inhaled therapy, true adherence to a recommended treatment regime is the product of regimen compliance × device compliance (is the device used at all) × (is the device used effectively).

If the device is not taken out of the drawer the inhaler technique is irrelevant, but true adherence can still be zero if the patient attempts to take the treatment in line with the prescribed pattern of use but the patient is unable to use the device effectively. Reasons for being unable to use the device (lack of competence) include lack of adequate instruction compounded by lack of reinforcement while for others ineffectual use is due to ignoring what they know and using it efficiently (contrivance—contriving to use it inefficiently), such as the patient who demonstrates a perfect technique with a pMDI spacer but who “knows” he does not need to use the spacer and simply fires it into their mouth while taking a rapid inspiration.

The importance of true compliance can be illustrated if one considers “difficult asthma.” In general, certainly in pediatrics, there are only three causes for difficult asthma in the vast majority of patients.

1. A misdiagnosis of symptoms being attributable to another condition all together, such as bacterial bronchitis.
2. Asthma and a comorbidity such as a persistent bacterial bronchitis (often secondary to poor control) or an intercurrent pertussis infection.
3. Ineffective drug delivery, which may be due to poor regime compliance or device compliance (due to lack of competence or contrivance).

For those who require regular therapy because of ongoing symptoms or significant exacerbations, the evidence suggests that adherence probably needs to exceed 80%—that is of a potential 14 doses a week (twice daily dosing) the patient should not miss more than 3 doses.[17a] Fewer than 20% of subjects who require this intensity of treatment appear to reach this threshold for a wide variety of reasons such as fear of side effects, concerns regarding development of “dependency,” and financial considerations. “Drug holidays” are frequently observed in clinical trials suggesting that patients are testing to determine whether medication is still required. However, the most commonly reported cause is simply forgetting to take the medication. Failure to develop a routine that deals with the need to take the medication regularly and with consistency is a common factor amongst those with poor compliance. Unfortunately, lack of explanation regarding the rational for adhering to regular medication and confusing messages from different health care professionals compound the problem. Until health care professionals are able to do the simple things well this situation is likely to persist.

Evidence suggests that competence and contrivance can both be addressed with effective education by healthcare professionals, but these messages need to be repeated and reinforced. Education has, in general, little or no impact on behavior in the vast majority of patients unless considerable resources are invested and to date, the most effective interventions appear to be monitoring with feedback. Studies that provide patients with feedback regarding their behavior have consistently shown improved adherence and studies that are more recent have started to demonstrate clinically important improvements resulting from the improved adherence. It seems likely that more devices will have data loggers incorporated or will be provided with an add-on data logger that can provide real time feedback. Improved data provides for more open and honest discussion between physician and patient.

## Assessment Techniques

Aerosol drug formulations and devices need to be assessed in combination because the formulation can greatly affect the type of aerosol emitted from a given device. These evaluations may be purely in vitro assessments of aerosol generation and efficiency of aerosol delivery, or in vivo measurements of drug delivery to the patient and deposition within the lungs. In general, these aerosol-specific assessments are conducted as part of the development and initial assessment of the performance of an inhaler, prior to conducting larger scale trials of clinical outcomes in different patient groups.

### Aerosol Generation

Assessment of aerosol characteristics with in vitro techniques consists of the measurement of those characteristics of the aerosol that have a major effect on drug delivery to the lungs. The efficacy of drug delivery from the aerosol generated by a particular device is largely dependent on two factors:

1. The range of particle sizes present in the aerosol cloud, termed the *particle size distribution*.
2. The total output of drug.

The size distribution of the particles or droplets making up a therapeutic aerosol can be described in three ways: the frequency of occurrence of particle volumes, masses, or counts. The description of the aerosol cloud can then be expressed as, respectively, the volume median diameter (VMD), the mass median diameter (MMD), and the count median diameter (CMD). These diameters are those above and below which, respectively, half the volume of the aerosol, half the mass of the aerosol, and half the number of particles in the aerosol reside. The VMD and the MMD will be identical if all the particles comprising the aerosol have the same density, as is normally the case when a drug in solution is nebulized. As the amount of drug contained within a droplet or particle is defined by the volume of the particle, and this is related to the cube of the radius of the particle, the CMD is not useful in assessing the likelihood of successful drug delivery from a therapeutic aerosol, as one droplet 5 μm in diameter will contain 1000 times as much drug as one droplet 0.5 μm in diameter and therapeutic aerosols are generally polydisperse, consisting of particles with a range of diameters. The particles may also be irregular in shape and differ in density, which will alter their behavior when entrained in an air flow. The aerodynamic behavior of a particle is best described by its aerodynamic diameter, that is, the diameter of a spherical particle of unit density that behaves in the same way when entrained in a defined air flow. Measurement of the MMAD, of an aerosol by inertial impaction, helps to describe and predict the behavior in an air flow of a polydisperse aerosol consisting of particles of different shapes and densities. The extent to which the aerosol is polydisperse is defined by the GSD ($\sigma_g$), the ratio of the particle diameter below which 84.3% of the mass is contained to that below which 50% is contained. The larger the GSD, the more polydisperse the aerosol. Most inhaler devices produce aerosols consisting of large numbers of small particles with progressively fewer larger particles, within the range of approximately 1–10 μm MAD.

All of these factors can be greatly affected by the way in which the inhaler is stored and used. Optimizing the particle size distribution and output from an inhaler by careful formulation, and good storage and use practice, will maximize the amount of drug available for inhalation by the patient.

## Particle Size Distribution

There are two main methods of assessing the particle size distribution from a given aerosol: inertial impaction and laser diffraction. Inertial impaction measures the actual drug content within particles of a precalibrated size range while laser diffraction measures particle size by volume. For most drug solutions and for dry powders consisting only of the drug compound, we may assume that the drug is evenly distributed through the aerosol droplet or particle.

### Inertial Impaction.

The generated aerosol is drawn by an entraining air flow (defined and calibrated for each device) through the impaction device, which consists of a series of stages. Each stage acts as a low pass filter, where "larger" particles, above the defined aerodynamic diameter cut-off for that stage, impact and are retained, while "smaller" particles remain entrained in the air flow to move further through the device. At each consecutive stage, remaining particles above the cut-off aerodynamic diameter of that stage are retained, while particles of smaller aerodynamic diameter remain entrained until they reach the final stage, which consists of an absolute filter to remove very small particles that have not impacted further up the series of stages.

There is a wide variety of impaction devices available. Cascade impactors collect particles in discrete size ranges that impact on a series of solid stages, sometimes coated with grease to trap the impacting particles and prevent them from bouncing off the stage, to be reentrained and drawn on to a lower stage. Liquid impingers have a layer of solvent on each stage (except the absolute filter), which performs the same function. Each impaction device may be made up of a different number of stages. The greater the number of stages, the greater is the resolution in the characterization of the particle size distribution of a particular aerosol. The particle size cut-offs for the stages in each impaction device are calibrated for a particular entraining air flow, which may also affect the characteristics of the aerosol. Particles reaching the lower stages of inertial impactors (with particle size ranges of around 1–5 μm) are often referred to as “respirable” particles, though the amounts of drug captured on these stages tend to be a significant overestimate of the proportion of drug emitted from the inhalation device that would reach the lungs of patients.[18,19] An example of two impaction devices, a multistage cascade impactor and the Next Generation Impactor (Copley, UK), are shown in Fig. 16.2.

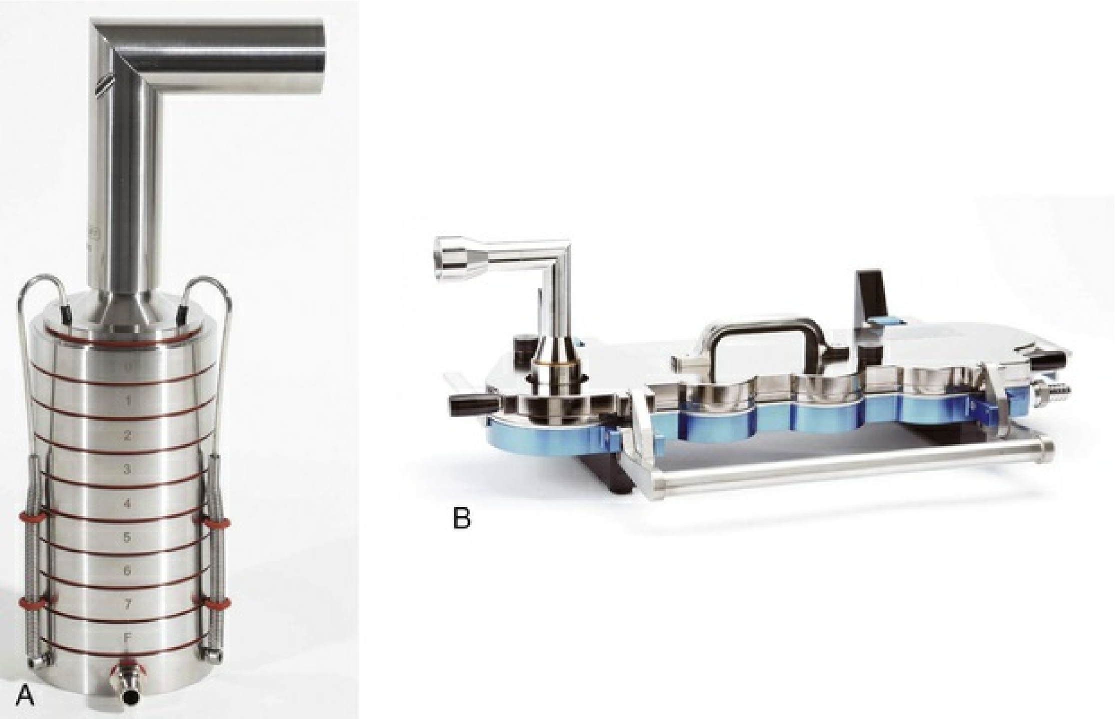

**FIG. 16.2** Examples of two most widely used impaction devices for measurement of particle size of aerosol drug-device combinations for regulatory approvals. (A) The Andersen Cascade Impactor and (B) the Next Generation Impactor. (From Copley Scientific Limited, http://www.copleyscientific.com/.)

Once the aerosol dose has been drawn through the device, the air flow is stopped and the surface of each stage is washed separately to remove impacted particles. The amount of drug retained on each stage is assayed, usually using high performance liquid chromatography or ultraviolet spectrophotometry. The sum of the amount of drug deposited on these stages provides the total drug output of the device tested. The components of the inhalation system, such as the pMDI actuator or the nebulizer body, may also be washed to measure the amount of drug retained by the device and not administered to the patient. Using this method, an assessment can be made of the amount of drug contained within each fraction of the total range of particle sizes contained within the generated aerosol, and hence a prediction can be made of the amount of drug that will reach the target area within the lungs. Any changes in particle size distribution and total drug output in the aerosol generated by an inhaler under different conditions, or with changes in formulation can also be assessed.

The particle size distribution is given in discrete ranges, not the continuous spectrum of sizes actually generated by the device being tested, which is a disadvantage of inertial impaction techniques. Hence, direct comparisons between different impaction devices are not easy, especially if they are calibrated for different entraining air flows.

### Laser Diffraction.

Measurement of particle sizes using laser diffraction involves passing the aerosol through a laser beam, resulting in light scattering (Fraunhofer diffraction) by the edges of the aerosolized particles. The scattered light passes through a lens that focuses the rays onto a series of detectors. The angle of diffraction is inversely proportional to the droplet size.[20] This information is used to calculate the numbers of aerosolized particles at any volume in the aerosol. This method only measures particle volumes (VMD) and not the actual amount of drug present. For aerosols generated from a solution of a drug, as produced by a nebulizer, the total volume of the combined droplets of any given size is proportional to the amount of drug contained within those droplets, and so may be useful in predicting therapeutic efficiency. For aerosols where the drug is contained within particles suspended in the aerosol, the particles may be larger than the smallest droplets, and so droplets in this range would contain no drug.

Measurement of particle size distributions using either of the techniques described above is complicated by a number of factors. Particle size distributions can vary greatly with the conditions of testing, such as inhalation flows through impaction devices, and driving gas flows through nebulizers.[21] Changes in particle sizes once an aerosol has been generated can also occur due to factors such as hygroscopic growth, which is dependent on humidity and the composition of the aerosolized particles,[22] and evaporation of the more volatile components of a drug suspension.

### Total Drug Output

The total amount of drug contained in a dose of aerosol generated by an inhalation system can be measured by delivering the aerosol through a low resistance filter, and assaying for the amount of drug deposited on the filter. Another method is measurement of the weight of the inhalation device before and after aerosol generation, but this method usually greatly overestimates aerosol output due to high levels of evaporation.[23] Total drug output, as well as the particle size distribution, can be determined using impaction devices, if the masses of drug in each size fraction are added together. This is not possible using laser diffraction techniques.

Factors other than particle size and output can also play an important role in the assessment of an inhalation system. In the case of nebulizers, the time taken to deliver the aerosolized drug is also important, especially in the pediatric age range. Factors such as driving gas flows through the nebulizer or inhalational flows through pMDIs, spacers, and DPIs can significantly affect all the parameters mentioned above.

## Delivery

In vitro studies under carefully controlled laboratory conditions are used to assess the aerosol generated by a particular device, giving relatively reproducible results. While these techniques provide useful information on optimizing aerosol generation, drug delivery from these same aerosol generation devices, to patients in a clinical situation, can still be extremely variable, largely due to variation in the patient's inhalation technique.

Filter studies can be used to assess aerosolized drug delivery to patients using different inhalation systems and inhalation techniques. For these studies, a low resistance filter is placed between the inhaler and the patient's mouth. When the device is actuated and the patient inhales, the amount of drug that would normally be inhaled by the patient is deposited on the filter. This equates to the “total body dose” that would have been administered to the patient. The filter can then be washed, and the amount of drug deposited can be assayed. This method is noninvasive, since the patients do not inhale any drug, and the performance of the inhaler can be assessed by measuring the “total body dose” delivered to the patient over a range of patients' breathing patterns. The approach provides some idea of the variability that inevitably occurs in the clinical use of these inhalers especially in children.[24] It does not however provide any information on the particle size distribution of the delivered aerosol, which can be influenced by inspiratory flow when using a nebulizer or dry powder inhaler, and gives no information about the pattern of deposition of the drug in the lung, mouth, throat, esophagus, and stomach that would have occurred if the filter was not present. To obtain information about where the inhaled drug deposits in the body, deposition scintigraphy by imaging following inhalation of a radioisotope labeled aerosol may be utilized.

## In vivo Deposition

Deposition scintigraphy is an imaging modality, which enables the investigator to visualize the in vivo distribution of drug within the patient's body. Two-dimensional (2-D) planar scintigraphy, three-dimensional (3-D) single photon emission computed tomography (SPECT), and positron emission tomography (PET) may all be utilized[25]; however planar scintigraphy involves the lowest radiation exposure and is generally the method utilized in children. The data obtained from scintigraphy studies takes into account both the drug-device delivery characteristics and the effect of the patients' inhalation techniques in determining the amount and distribution of aerosolized drug depositing within the body.[26–28] The drug is labeled with a low level of a radioisotope and gamma scintigraphy is used to quantify the deposition of the label in the lungs after inhalation by the patient. These tests are necessary to ensure that the aerosolized drug produced by an inhaler is reaching the target site, and the number of such studies should be minimized by only performing them with optimal delivery systems. Hence, initial assessments of any new inhaler should be carried out using in vitro and filter studies.

The most common radioisotope used for aerosol deposition studies is technetium ($Tc^{99m}$), a gamma emitter that has a short half-life of 6 hours. The half-life in the lungs is much shorter than this, about 15–20 minutes, as the isotope is rapidly cleared from the lungs. Mouth and throat deposition can be reduced by the use of a spacer with radiolabeled pMDIs, as well as mouth washing and gargling after inhalation of the radiolabeled aerosol.

Useful results can be obtained from images obtained after administration of a very low amount of activity (for planar scintigraphy) (Fig. 16.3), comparable to the radiation exposure received during a 12 hour plane flight, or from two to four weeks of exposure to natural background radiation.

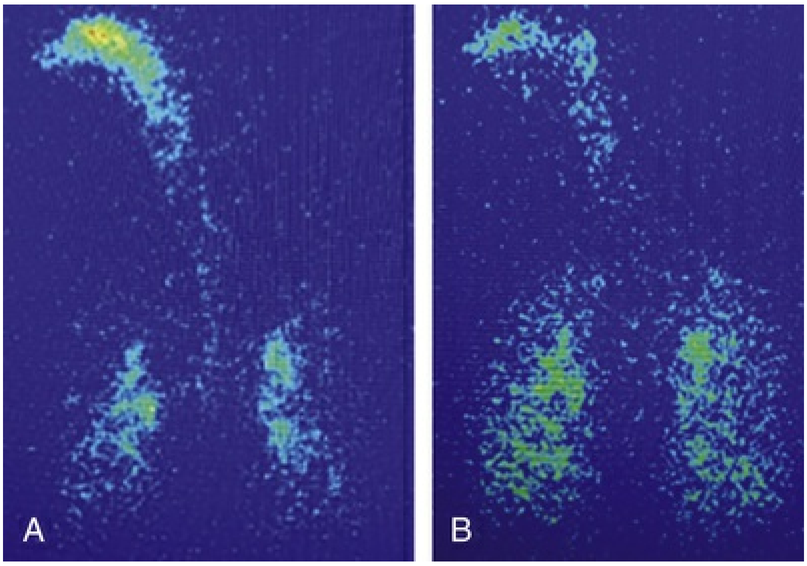

**FIG. 16.3** Examples of gamma scintigraphic images of an 15 year old asthmatic patient, obtained after inhalation of a radiolabeled aerosol from a pMDI, used (A) without a spacer and (B) with a spacer. The images capture the distribution of the label, $Tc^{99m}$ only, hence it

is critical that the radiolabeling method is carefully validated to ensure that the label “follows” the drug when aerosolized, prior to use in patients. The validation method utilizes the measurement of the aerosol particle size distribution using impaction devices, such as those shown in Fig. 16.2. Note the higher oropharyngeal deposition when the pMDI was used without a spacer.

Studies to observe the deposition patterns obtained when using nebulizers generally involve adding the required amount of radioisotope to give detectable deposition to saline or a drug solution in the nebulizer bowl.[29,30] Labeling of drugs in metered dose inhalers (both pMDIs and DPIs) is more difficult, and requires stringent validation of the labeling technique to ensure radioactivity comigrates with the administered drug, and hence is a good proxy for it, prior to administration to patients.

There are a number of techniques for labeling drugs in pMDIs,[31–33] most of which are based on the original method of Kohler.[34] The success of each labeling method depends on the drug formulation being used.[6] The labeling technique for drugs administered as a dry powder, used in inhalers such as the Turbuhaler, involves drying of the radiolabel onto the surface of the drug particles.[18,35]

To ensure that the radiolabel detected by scintigraphy is indicative of where drug has deposited in vivo, the effect of radiolabeling on the commercial aerosol must be minimal, and this and the comigration of radiolabel and drug must be confirmed in vitro.[36] In order to do this, firstly, the particle size distribution of the aerosolized drug in the commercial formulation is compared to that of the same drug formulation following radiolabeling. The second step is to ensure that the radioisotope also comigrates with the drug in this formulation. This is done by comparing the particle size distribution from assay of both the drug, and the radiolabel activity in the labeled formulation, by cascade impaction of the radiolabeled aerosol, and measurement of the activity in each fraction, followed by assay of the drug in each fraction when radioactivity has decayed to undetectable levels. More stringent guidelines for the validation of radiolabeled inhalers including limits for the comparison of the commercial to the radiolabeled inhaler have been published following consultation with a committee of international experts.[37,38] Following these guidelines is necessary to ensure that results from measuring the deposition of the radiolabel are a good proxy for the distribution pattern of the drug.

Using deposition studies, the proportion of the inhaled drug deposited in the airways, as well as oropharyngeal and gastric deposition, can be imaged using gamma scintigraphy to detect the radiolabel as a proxy for the drug. Attenuation of the gamma rays by body tissues is accounted for by calculating the attenuation of the counts obtained from a planar flood source by the body of the subject prior to inhalation of the radiolabeled aerosol. A measure of the penetration of the administered activity, and by association the drug, to the peripheral airways is made by calculating the amount of drug deposited centrally in a defined region of interest on the image, and comparing this to the total deposition seen in the same lung image.

Although the risk to the subjects from inhaling radiolabeled aerosols is low, there is still a risk associated with any exposure to radioactive materials, and the number of patients subjected to this form of testing should be minimized.[39] Preliminary noninvasive testing is still required for many drug formulations to characterize the type of aerosol generated by the delivery systems.

## Aerosol Devices

The three broad groups of devices used for inhalation therapy are

1. pMDIs

These may be patient actuated (frequently prescribed with a holding chamber to address some of the problems that are inherent with this type of device) or breath actuated.

Conventionally these have contained suspension-based formulations but some of the HFA formulations are solution based. To date it is has not been shown that there are any inherent advantages of one type of formulation over the other.

2. DPIs

These may be single or multidose devices and vary in their flow dependence (the extent to which changes in inspiratory flow affect the efficacy of drug dispersal). While debated, there is again no clear benefit attributable to those devices that have a high or low flow dependency providing the patient can generate flow sufficient to reach the minimum desirable flow. All current devices are dependent on the patient to provide the energy to aerosolize the drug (though a patient independent device was briefly marketed during the past decade for the delivery of inhaled insulin).

3. Nebulizers

These generate a "wet" aerosol usually from a solution formulation and include conventional jet nebulizers, ultrasonic and, increasingly vibrating mesh devices.

## Pressurized Metered Dose Inhalers

pMDIs have long been the most widely used form of asthma therapy in adults and older children, and are now the method of choice in infants and children under 5 years old (Fig. 16.4), when used in combination with an appropriate small volume spacer and, if required in young children, a well-fitting facemask.[27] pMDI canisters contain the drug, in suspension or solution in a propellant with surfactants, under high pressure (300–500 kPa, 40–70 p.s.i.). Chlorofluorocarbons (CFCs) were used as propellants in pMDIs, but these have now been replaced with HFAs, which are less destructive to the ozone layer. More than 99% of the dose from a typical inhaler consists of propellant, and so this must be nontoxic to the patient, as well as fulfilling the other requirements: having a low boiling point, a high vapor pressure, and a density close to that of the drug to be delivered.[40] Aerosols generated by pMDIs using HFA propellants in the formulation have very different properties, which sometimes increase the efficacy of these formulations. HFA propellants can be used to radically alter the particle size distribution of drug formulations, particularly from corticosteroid inhalers.[41] Some formulations have changed from a suspension to a solution of the drug, and MMADs can be decreased to as low as 1 μm. The character of the emitted plume is different, being warmer and softer, and this can decrease unwanted deposition in the mouth and throat due to lower particle velocities on activation. Lung deposition patterns detected in radiolabel deposition studies have been shown to be greatly altered by changes in the particle size distribution of inhaled aerosols.[30] Surfactants such as phospholipids or oleic acid are included in the formulation to increase bioavailability of the administered drug by decreasing the surface tension of the fluid lining the airways. Low concentrations of ethanol are sometime included to modify droplet surface tension and thus modify particle size distribution of the generated aerosol.

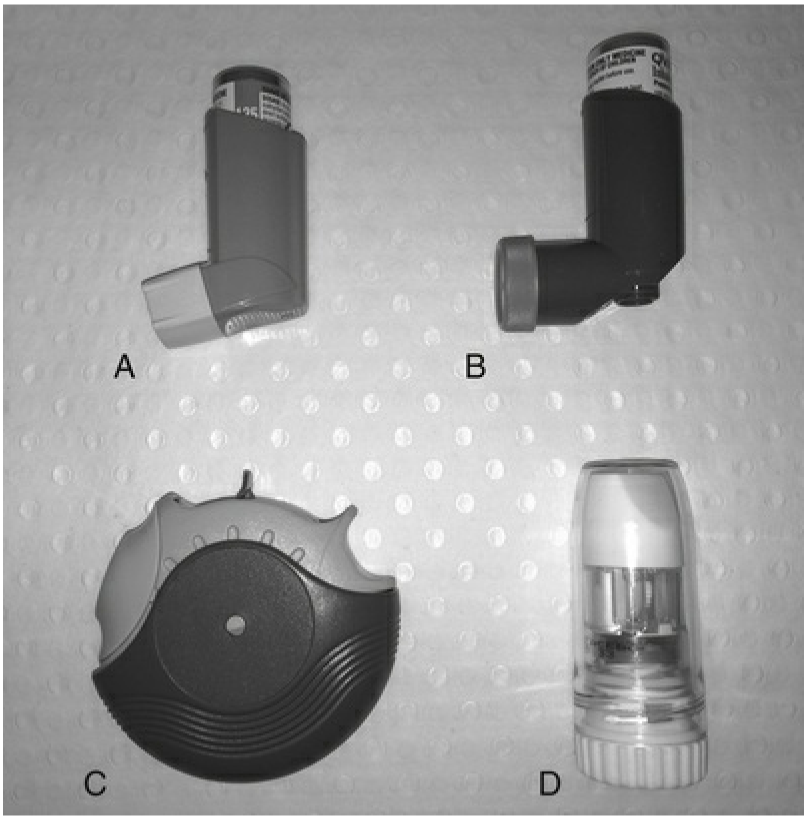

**FIG. 16.4** Examples of two types of pressurized metered dose inhalers (A, B) and two DPI types—the Accuhaler or Diskus (C), and the Turbuhaler (D).

Prior to actuation of the pMDI, the dose, still under high pressure, is contained within the metering chamber (Fig. 16.5). For drugs that are not in solution, the canister must be shaken immediately prior to actuation to resuspend the drug particles uniformly in the propellant. When the valve is opened to the atmosphere, the propellant expands and the suspension in the metering chamber is expelled at high velocities, up to 30 m/s. Initially, the particles are very large, up to 20 μm in diameter, but rapid evaporation of the volatile propellants reduces their size. This initial high velocity in conjunction with the larger particle sizes results in a sizeable proportion of particles impacting in the mouth and throat before the propellant evaporates, both decreasing the number of particles available for inhalation and deposition in the lungs and increasing the local oropharyngeal exposure and, potentially, the systemic dose. As mentioned above, some formulations using HFAs as propellants decrease oropharyngeal deposition due to the softer plume and smaller MMAD of aerosols generated from pMDIs using this propellant.

**FIG. 16.5** Schematic of a pMDI.

Patient-dependent problems, such as difficulty in coordinating actuation and inhalation, are common with the use of pMDIs.[42] For inexpensive drugs such as bronchodilators, which are mostly given in supramaximal doses and have few, relatively mild systemic side effects, this is of little importance. However, for drugs such as corticosteroids, it is critical to reduce local and systemic side effects (particularly in the pediatric age group) and to maximize lung deposition for several reasons: achieving the maintenance dosage is important, side effects such as oral candidiasis and hoarseness can occur with repeated oropharyngeal deposition, and these drugs are generally more expensive. Device-based problems include variation in the administered dose. An increase in drug concentration can occur following multiple actuations without shaking with the canister held in the inhalation orientation whereas a decrease in drug dose can occur if the metering valve is refilled with propellant alone, as drug settles out leaving only propellant to fill the metering chamber. Use of pMDIs at very low temperatures can reduce the vapor pressure above the propellant and thus decrease the efficiency of plume generation upon actuation, as well as decreasing the propensity of the initial large propellant droplets to evaporate to a size more conducive to penetration to the lungs, depositing instead in the mouth and throat. Inhalers using HFA as a propellant are less prone to ambient temperature related problems,[43] although this may not be the case for all HFA inhaler formulations.[44]

Patient dependent problems can be reduced by the use of spacers, also termed *holding chambers* or *extension devices*.[45] These are generally made of plastic (although a metal spacer is available). The pMDI actuator is inserted into an opening at one end and aerosol inhaled through a mouthpiece or facemask with a one-way inspiratory valve at the other end. As there is more time for the propellant to evaporate before entering the mouth or nose, and there is a greater distance between the actuator and the patient's mouth, smaller particles are eventually inhaled, with a reduction of impaction of particles in the mouth and throat. Infant spacers have been developed for use with a facemask. These contain a separate expiratory valve, which allows younger patients in particular to use tidal breathing for inhalation, and have smaller volumes (150–250 ml) that only require 5–10 tidal breaths by the infant to be emptied.

The problem of coordination can be overcome by using breath-actuated pMDIs, such as the Autohaler. However, they require a minimum inspiratory flow to be actuated, which makes them difficult to use for younger children, and higher levels of oropharyngeal deposition can occur, as these devices cannot be used with spacers.

The recommended optimal inhalation technique when using a pMDI without a spacer is a slow maximal inhalation with actuation of the pMDI as the slow inhalation is commenced. The pMDI is held between the teeth and with the lips sealed around the mouthpiece. The inhalation is followed by 10 second breath hold to increase sedimentation of particles.[46,47] An open mouth technique where the pMDI is held 2–3 cm from the open mouth and actuated at the start of the inhalation may help to reduce oropharyngeal deposition as the plume has a chance to slow and particles to decrease in size by evaporation before entering the mouth. This reduces the ballistic impaction of particles in the upper airway. The slow inhalation and resulting low air flow can reduce inertial impaction of large particles. As infants and young children are unable to perform this maneuver, they inhale aerosols by tidal breathing through a spacer. The use of spacers is essential in this age group even for delivery of bronchodilators.

Drugs for the treatment of asthma such as bronchodilators, corticosteroids, and sodium cromoglycate, are often delivered by pMDIs, particularly in younger children.

As noted previously, calculating the most appropriate device for use with a pMDI/spacer is not easy. Currently, adult doses of inhaled asthma medication are being given to infants and young children. This practice may mean that children are receiving a much higher dose for their size than adults. On the other hand, differences in inhalation patterns and tidal volumes could mean that the dose delivered to young children will be size corrected. There is some evidence that lung deposition in children under 5 years of age using a pMDI with a small volume spacer is only about 2% of the nominal dose,[48] whereas in a 70 kg adult it may be up to 20% of the nominal dose, giving similar dose rates per kilogram of body weight.

There is an extensive body of literature on the optimal use of pMDIs and their accessory devices.[49–53] Factors such as temperature,[54] altitude,[55] and storage conditions[56] can affect the performance of pMDIs, while the aerosol output from spacers is greatly affected by factors such as multiple actuations,[57,58] spacer volume and valve design,[57,59] and time delays between actuation and inhalation.[60] Static electricity buildup on the spacer wall can result in the loss of up to 50% of an aerosol dose, but this can be minimized by using a charged detergent to clean the spacer. The extent of practical application of this knowledge is still unclear.[61,62] Static is not a problem with metal spacers.[57]

## Dry Powder Inhalers

There are many advantages to DPIs, including their portability, the lack of a requirement for coordinated actuation and inhalation, and the relative simplicity of construction of some types.

DPIs are used to deliver a similar range of drugs as pMDIs. The aerosols generated by these devices consist of solid drug particles and carrier, dispersed in air. The DPIs most commonly used commercially are breath-driven, and so do not require coordination of actuation and inhalation as pMDIs do. DPIs generally require a mid-high peak inspiratory flow (PIF) to deaggregate and suspend the drug particles into the air flow. Small particles less than 5 μm in diameter, produced by milling or spray drying, tend to clump together due to electrostatic forces, and exhibit poor flow characteristics. Inclusion of an excipient such as lactose in the formulation can loosely bind these small respirable drug particles to larger carrier particles of about 30–60 μm diameter, which exhibit much better flow characteristics, allowing a forceful inhalation to draw the drug and excipient through a turbulence-inducing device, which deaggregates the drug from the excipient as the dose is suspended in air. The smaller drug particles are then free to be drawn down to the lungs, while the larger excipient particles impact in the mouth and throat. Increased inspiratory effort generating higher PIFs will optimize the particle size of the drug output. Although high PIFs generally increase the impaction of particles in the oropharynx, this effect is offset by the much reduced drug particle size range due to more effective deaggregation. Flows less than the minimum required to deaggregate the drug and excipient will lead to poor pulmonary deposition. Children, especially those who are unwell, are often not capable of producing sufficient flow to successfully deaggregate the powder and, in addition, the total volume of the inspiration may not be sufficient to draw powder deep into the lungs to the therapeutic site of action. DPIs are not recommended for young children under five years of age.

Variable drug delivery associated with the use of DPIs can arise in several ways. These include inadvertently tilting the device so that the powder falls out, or exhaling through the device, thus blowing out the powder prior to inhalation.

Two of the most widely used DPI types are the Accuhaler (or Diskus) and Turbuhaler. The Accuhaler (see Fig. 16.4) utilizes individual doses of drug combined with lactose as a carrier, sealed in blisters on a medication disk. Each blister is pierced within the device just before inhalation. The Diskus delivers a fairly uniform drug dose with patient inspiratory flows between 30–90 L/min.[63] The Accuhaler is also a lower resistance device, so it may be easier for children to achieve the required inspiratory flows.

The Turbuhaler (see Fig. 16.4) is a reservoir device where the drug is stored in the form of spheronized, micronized particles, which do not require a carrier. The metered dose is dispensed from the reservoir into the dosing chamber at the base of the channel, through which the drug will be inhaled, by twisting the base of the device. As the drug is inhaled, the spheronized drug particles are broken up into smaller “respirable” particles, as they are pulled through the spiral disaggregation channels in the mouthpiece. The greater the PIF generated by the patient, the smaller the overall particle size range of the aerosol produced by the device.[64–66] The output of this type of device is affected by many factors, which have also been studied in detail.[67,68] One important recommendation is that the peak inspiratory flow should be achieved by the patient as early as possible in the inspiratory maneuver, as this markedly reduces the particle size of the deaggregated drug, which is likely to increase the amount of drug reaching the lungs.[69]

Patients must be able to generate flows of at least 30 L/min while using the Turbuhaler to achieve a good clinical response[70] but flows of 60 L/min are considered optimal.[63] While it is a high resistance device, making it more difficult for patients to achieve the required flows, children greater than 6 years of age have been shown to be able to use it optimally with appropriate training.[71] Lung deposition does not appear to increase with flows greater than 60 L/min. Young children (younger than 5 or 6 years of age) are generally unable to use this device optimally since (a) their inhalation technique is not reliable (they may blow into the device rather than inhaling) and (b) they may not be able to consistently generate the required peak inspiratory flow. Infants are obviously unable to use this device.[72]

In adults, when used optimally, lung deposition using this device[18,19] is higher than that of other DPIs[33] and nebulizers,[73,74] and similar to optimal values using a spacer in conjunction with a pMDI.[75]

## Nebulizers

Nebulizers can be used to deliver a wide range of drugs, in both solution and suspension formulation (i.e., a single nebulizer unit can be used to deliver multiple drugs). Metered dose inhalers (pressurized and dry powder), on the other hand, are specific for a drug-device combination and involve a high cost during the R&D phase and, in the postdevelopment phase, testing is required to obtain regulatory approval. Hence, aerosolized drugs for diseases such as cystic fibrosis are most often delivered via nebulizer.

However, it is now recognized that because of the large variability in delivery from different nebulizer types, safety and efficacy testing (particularly of new drugs) needs to take into account the specific drug-nebulizer combination being used. For example, the product literature for Pulmozyme (dornase alpha) includes a list of recommended nebulizers, and specifies the compressors to be used with each of the recommended jet nebulizers.

Nebulizers may not be ideal devices to generate a therapeutically effective aerosol from a novel drug formulation. This could lead to overdosing or underdosing of the lung as nebulizer performance can vary widely when used to aerosolize a drug either not intended to be delivered in an aerosolized form, or designed to be used in a different nebulizer. Off-label use of drug and/or delivery devices with a failure to match the drug to the delivery device can lead to problems.

Drugs such as antibiotics (tobramycin) used in the treatment of *Pseudomonas spp.* lung infections have comparatively high MICs and the large volumes required to achieve a therapeutic concentration at the site of action preclude their use as a pMDI formulation. More potent drugs such as those used in the treatment of asthma require far less total dose; hence the widespread use of pMDI formulations for asthma. Thus nebulizers generating a "wet" aerosol are the device of choice for many drugs.[76]

Jet nebulizers have been used for many years for the treatment of respiratory disease (Fig. 16.6). Drug formulations for jet nebulizers are generally aqueous solutions, although some drugs are dispensed in the form of suspensions (corticosteroids) or viscous solutions (antibiotics). The simplest of the nebulizer designs is the T-piece jet nebulizer (Fig. 16.7). An aerosol is generated by passing air flow through a Venturi in the nebulizer bowl. This forms a low-pressure zone that pulls up droplets through a feed tube from a solution or suspension of drug in the nebulizer bowl, and in turn this creates a stream of atomized droplets, which flow to the mouthpiece. Higher air flows lead to a decrease in particle size and an increase in output. A baffle in the nebulizer bowl is impacted by larger particles, retaining them and returning them to the solution in the nebulizer bowl to be reatomized. There is considerable variation in the performance of nebulizers.[77] In addition, nebulizers require a source of compressed air, which make them bulkier and more inconvenient to use than other inhalation systems.

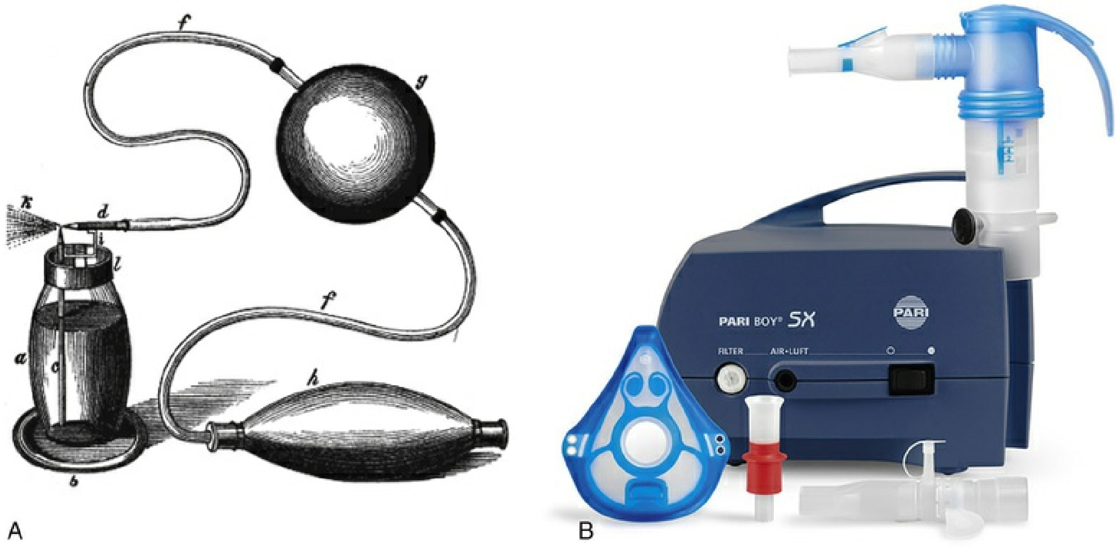

**FIG. 16.6** Jet nebulizers old and new: An example of one of the very early jet nebulizers (A, Bergson's apparatus with the foot bellows) and an entrainment or breath-enhanced nebulizer and compressor currently in widespread use, the LC Sprint with the PARI Boy SX compressor (B). ([A] Reused from Beatson G. Practical papers on the materials of the antiseptic method of treatment, vol. III, on spray producers. In: Coats J, ed: History of the Origin and Progress of Spray Producers, Glasgow Medical Journal, edited for the West of Scotland Medical Association, July to December 1880, Vol. XIV. Glasgow: Alex and Macdougall, 1880, pp 461-484, 463. [B] From PARI Respiratory Equipment, Inc. https://www.pari.com/us-en/products/nebulizers/.)

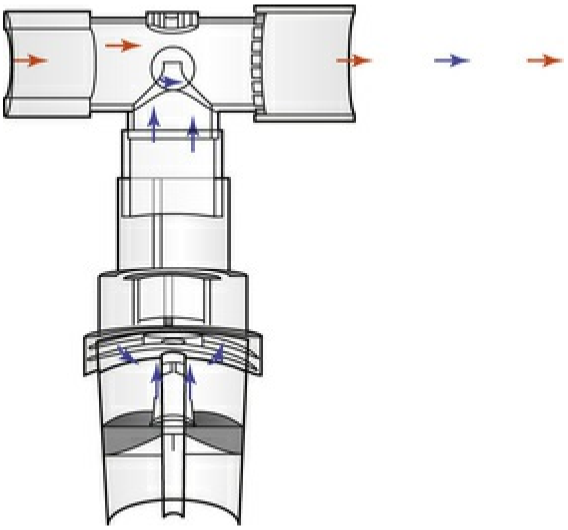

**FIG. 16.7** A schematic of a T-piece jet nebulizer. Air under high pressure passes through a small hole as it expands, and the negative pressure generated sucks the drug solution or suspension up the feeding tube, where it is atomized. The atomized drug either impacts on the baffle, returns for renebulization, or leaves the nebulizer.

Another solution to increase total drug delivery and improve deposition was the storage of aerosol generated during expiration in a holding chamber.[73,78,79] These solutions proved inconvenient for widespread use, increasing nebulization times and making the delivery systems even more bulky and cumbersome.

Entrainment of air through the nebulizer bowl as the patient inhales has been shown to increase aerosol output during inspiration.[80] The development of nebulizers utilizing this principle (entrainment or breath-enhanced nebulizers) (Fig. 16.8) have been shown to result in increased deposition.[81] These "entrainment" jet nebulizers are now commonly used for long-term delivery of aerosol medications for diseases such as cystic fibrosis (see Fig. 16.6). Fig. 16.9 shows the increase in colistin delivery resulting from the use of an entrainment nebulizer compared with a standard T-piece jet nebulizer.

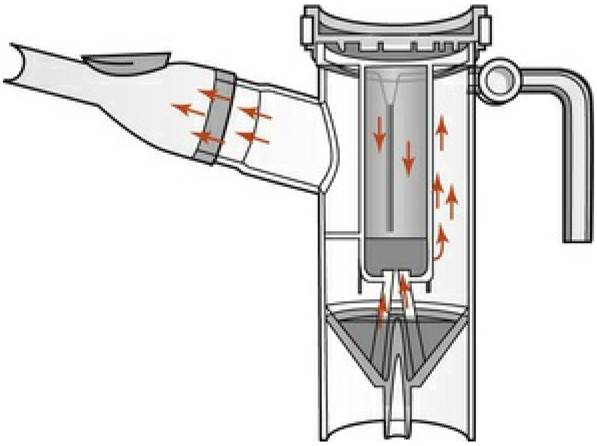

**FIG. 16.8** A schematic of an entrainment or breath-enhanced nebulizer. A vent at the top of the nebulizer opens when the patient breathes in, thus allowing extra air to be entrained through the device. This extra air carries with it more aerosol than would normally have been deposited within the device and renebulized. Drug delivery is increased, as proportionately more drug is inhaled during inspiration than is lost during the expiratory phase when the valve at the top of the nebulizer closes.

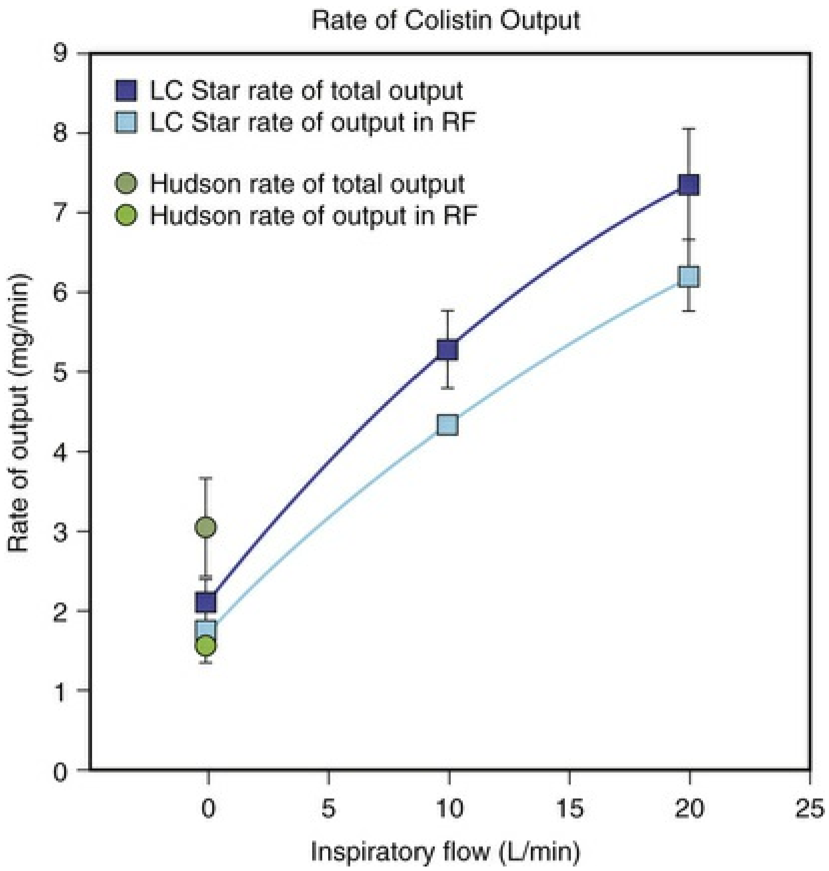

**FIG. 16.9** The rate of output of colistin from an unvented (Hudson Updraft II) and a breath-enhanced (PARI LC Star) nebulizer in relation to entrained flow. The breath-enhanced nebulizer dramatically increases the rate of output (both total and that in the respirable fraction), whereas the inspiratory flow (entrained flow plus nebulizer driving flow) has no effect on the unvented nebulizer. *RF,* Respirable fraction. (Modified from Katz SL, Ho SL, Coates AL. Nebulizer choice for treatment of cystic fibrosis patients with inhaled colistin. *Chest*. 2001;119:250-255.)

The duration of nebulization ranges from 5 to 20 minutes, depending on the type of nebulizer and the volume of drug formulation in the nebulizer bowl.[82] Generation of an aerosol with a smaller particle size distribution is desirable, but using a nebulizer designed to do this can result in an increased nebulization time. Tapping the nebulizer bowl during nebulization results in increased total drug output as larger droplets deposited on the walls of the bowl are shaken back into the main volume of drug solution, but this also increases the nebulization times.[83] The “dead volume” of jet nebulizers containing the residual drug solution that cannot be nebulized also results in wastage of drug. Any evaporation of the solution in the nebulizer bowl during nebulization means that the concentration of drug in the dead volume is higher than that in the aerosol generated.[83] If saline is used to dilute the nebulization solution, drug wastage can be reduced at the expense of increased nebulization times.

Children usually inhale the aerosols generated by these nebulizers using tidal breathing, although some reports suggest that deep inspirations, either with or without breath holding, would give better results.[84–86] Administration via a face mask that allows nasal inhalation, or a nasal mask, has been shown to greatly reduce lung deposition,[87] since the nose is much more efficient than the mouth in filtering out any particles with a diameter greater than 1 μm.

A further development in nebulizer technology is the vibrating mesh nebulizer, also now commonly used for long-term nebulizer therapy. These were developed in the early 2000s. In these devices the vibration of a piezoelectric crystal is not used directly to generate the aerosol, but rather used to vibrate a thin metal plate perforated by several thousand laser-drilled holes (Fig. 16.10). One side of the plate is in contact with the liquid to be aerosolized, and the vibration forces this liquid through the holes, generating a mist of tiny droplets. By altering the pore size of the mesh, the device can be tailored for use with drug solutions of different viscosities, and the output rate changed. Mesh nebulizers are powered either by mains electricity or by battery, are more portable than jet nebulizers, and they are silent in operation, in contrast to the rather noisy compressors used to drive jet nebulizers. Output rate is higher than that attained by a jet nebulizer, and a higher dose can be attained in a short time.[88]

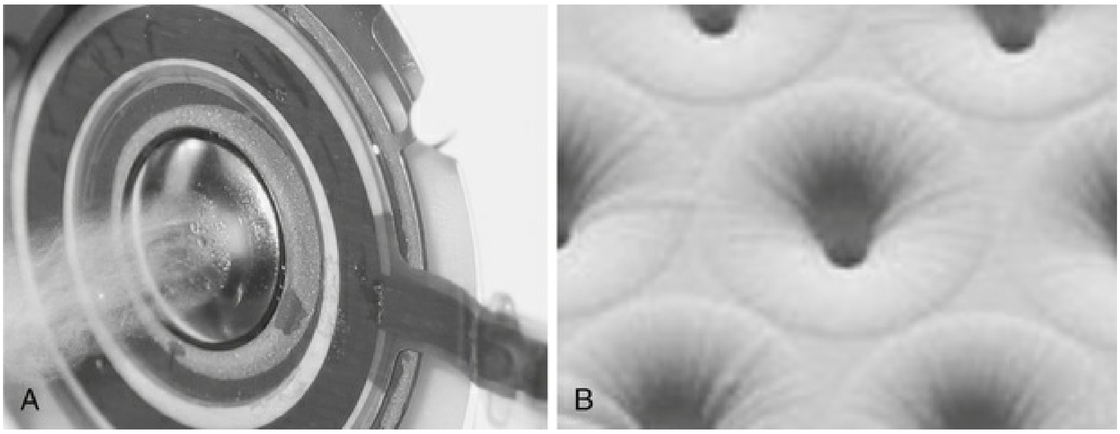

**FIG. 16.10** Examples of the vibrating perforated-membrane technology used in mesh nebulizers. (A) The aerosol generator from a Pari eFlow device shows the aerosol being generated from the “mesh,” which is driven by the surrounding piezo element. (B) A magnified view of a perforated membrane used in Aerogen nebulizers is shown.

Nebulizers can also be used to provide feedback to the patient to indicate when correct use has been achieved and to reinforce optimal inhalation technique. The I-neb (Respironics) operating in targeted inhalation mode provides audible and tactile feedback that informs the patient when the dose has been correctly delivered, thereby improving adherence.[89]

Refinements of standard jet and vibrating mesh nebulizers are aimed at both increasing lung deposition rates of drug, and reducing waste of the drug during expiration, as conventionally, the aerosol is continuously generated. This is important when treating children, as compliance with instructions on how to breathe can be reinforced by active feedback from the device being used. Breath activated nebulizers detect the patient's inspiratory flow and only release aerosol when the flow is sufficient to open a valve (AeroEclipse, Trudell Medical International, Ontario, Canada). Breath-controlled nebulizer compressors, such as the Akita (Activaero, Gemunden, Germany), monitor the child's breathing pattern and only generate aerosol during the phase of the respiratory cycle when inspiratory flows are conducive to drawing the aerosol into the lungs (Fig. 16.11). The duration of the inspiratory flow on triggering can be set, to encourage slow and deep breathing by feedback from the device.[90] A refinement of this is adaptive aerosol delivery, where the device such as the I-neb (Respironics) "learns" the child's breathing pattern and tailors the release of the dose to match the individual breathing pattern.[91] These enhancements of the aerosol delivery process decrease the wastage of drug, which is increasingly important with expensive new peptide and recombinant protein drugs, as well as improving targeting of the inhaled drug to the site of action, by only introducing aerosol into the inhaled air flow when the flow rate is optimal to target the desired region of the lung region with the particle size being generated.

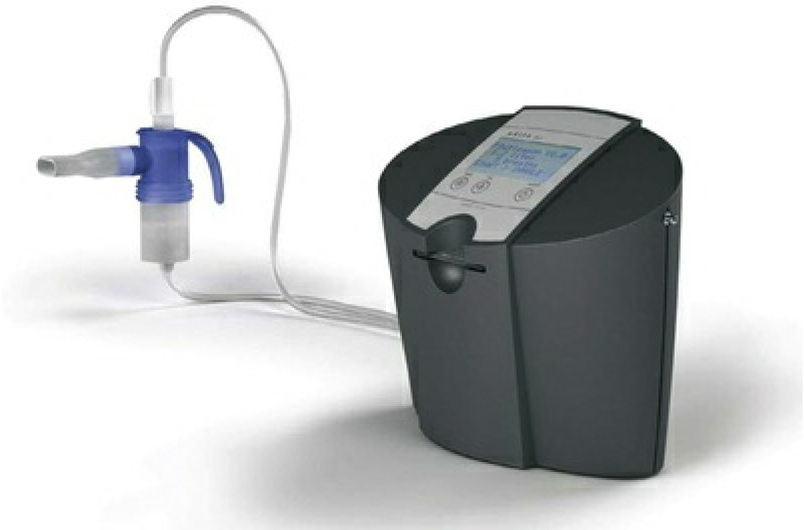

**FIG. 16.11** The device is breath-actuated and it guides the patient to inhale with a pre-set inspiratory flow rate and inhalation time to ensure precise and targeted drug delivery to the child's lungs. (From Vectura plc Group, http://www.akita-jet.de/en/.)

Ultrasonic nebulizers generate aerosols using the vibration of a piezoelectric crystal, which is transferred to the drug solution. The solution breaks up into droplets at the surface, and the resulting aerosol drawn out of the device by the patient's inhalation, or pushed out by an air flow through the device generated by a small compressor.[92] Ultrasonic nebulizers are not suitable for suspensions (corticosteroids) or viscous solutions (antibiotics) since very little drug is carried in the aerosolized particles,[80] and hence they have a more limited application than mesh nebulizers. Droplet sizes tend to be larger with ultrasonic nebulizers than with jet nebulizers.

Small volume liquid inhalers such as the Respimat (Boehringer Ingelheim, Ingelheim, Germany) are devices that use a spring to provide the energy to nebulize a small-metered volume of liquid, analogous to the metered dose produced by actuation of a pMDI. The energy in the spring is used to push a small volume of drug solution through a Venturi, generating a soft wet aerosol plume of about one second duration. The slow generation decreases the requirement for accurate coordination of actuation and inhalation, making it easier to use than a pMDI. Efficiency of drug delivery to the lungs is high, up to 40% of the nominal dose. However, the volume of liquid nebulized is only 15 μl, making it only suitable for drugs with high potency and low dosage mass.[93]

## Devices for Use in Mechanically Ventilated Patients

Delivery of aerosols to patients who are mechanically ventilated presents numerous challenges. Many factors conspire to decrease the efficiency of drug delivery to mechanically ventilated patients, such as timing of actuation of the pMDI in relation to ventilator air flow, placement of the in-line adaptor or spacer in the circuit, heat and humidity of the air flow in the ventilator circuit, and density of the inhaled gas[94] A recent international survey of intensive care physicians concluded that optimal administration of aerosols generated by pMDIs or nebulizers was rare.[95] T-piece jet nebulizers often used to administer aerosolized drugs to noninvasively mechanically ventilated patients are notoriously inefficient and deliver less than 10% of the nominal dose to the lungs.[29,73,74] Reasons for this include large deadspace volumes and wastage of aerosol during expiration.[59,96] To overcome this problem, nebulizers were developed with interrupters[8,97] and dosimeters[80] so that aerosol is only generated during inspiration.

Invasively ventilated pediatric patients under anesthesia who suffer a bronchospasm during surgery require prompt administration of a bronchodilator. In-line pMDI actuators are often poorly designed, leading to breakage of the pMDI valve stem on actuation, and in-line spacers with too large a volume can take too long for adequate clearance by pediatric tidal breathing patterns. Often the route of administration of choice is to actuate a pMDI directly into the end of the endotracheal tube (ETT), but this requires breaking into the ventilator circuit and problems can occur due to changes in the design of the pMDI and actuator.[98] A nebulizer can be inserted into the circuit ready to be used if required.[99] Furthermore, drug can bind to the plastic of the ETT, leading to little or no drug reaching the lungs when an aerosol is delivered either via an in-line adaptor in the circuit, or by breaking into the circuit and administering drug directly into the connector. Many actuations of the pMDI are required to achieve bronchodilation, and the drug has to be administered during the ongoing surgical procedure. Devices such as the Microjet,[100] which generate the aerosol at the tip of the ETT, present a possible solution.

# Dosage Considerations

## Calculating Dose

Despite large losses of emitted dose observed across devices, aerosol drug delivery remains the mainstay of respiratory care. Research and development continues to increase the efficiency of aerosol delivery systems. The early T-piece jet nebulizers delivered less than 10% of the drugs to the lungs. Lung deposition with current inhaler devices can be as high as 50%–60% when optimally used, even in children.[26,101] Improved drug deposition and dosage has resulted from a range of factors, including drug delivery device design and use of different formulations, including ratio of propellant.[102]

### Aerosol Drug-Delivery Device Design

The oropharynx is the largest site of inhaled dose loss due to adsorption because of impaction observed for pMDI and DPIs. This can be as high as 80% of the total loss with the remaining 20% lost to mouthpieces and poor technique.[102] The addition of holding (spacer) devices and good technique can improve delivery by as much as 5%–10%. Nebulized drug delivery is mostly lost to the surrounding environment and therefore it requires a greater starting dose.[102] Few studies exist to compare all three major types of devices in order to create a standardized matrix to ensure equivalent prescribed doses. A single study comparing a starting dose of 5 mg of bronchodilator delivered using a jet nebulizer to 400 μg delivered via pMDI and DPI to severe asthmatics showed comparable increases in FEV1.[103]

### Patient Considerations

Smaller air passages of infants is a likely cause of large (up to half) nebulized aerosol losses in their noses compared to older children.[29,104] Drug delivery in noncooperative infants may be negligible due to reduced time spent inhaling, or by maintaining inadequate contact with facemask or delivery device; demonstrating the importance of patient cooperation in efficient drug delivery.[9,59,67] For these reasons, it is also clear that smaller breath size is not the only cause of lower aerosol drug dosage. It is likely that infants and young children receive much the same dose from a given device, when size-corrected using either body weight, lung volume, or airway surface area.[105–108]

Estimating dose for children is not easy given size variation within age groups, and clinical responses are not a reliable measure that can be used in this age group to determine appropriate dose.[9,109,110] As noted before, delivery is highly dependent on device, highlighting consideration of device choice with respect to its use in a particular age group and individual capability. In particular, it is difficult to find noninvasive clinical measures or outcomes that can be used in very young children, and are sensitive enough to detect differences in therapeutic efficacy when comparing different devices or dosage regimes.[111]

## Minimizing Systemic Dose From Inhaled Drugs

Inhalation via the mouth to avoid nasal absorption of drugs[104] and avoiding swallowing for delivery systems with high oropharyngeal deposition will both minimize systemic absorption. Mouth washing can be also be used to help reduce ingestion of drugs from the oropharynx. This is especially important for drugs such as fluticasone where any swallowed drug is not likely to reach the systemic circulation; first pass metabolism to an inactive metabolite is almost complete.[112]

# Advice and Training for Parents

## Role of the Clinician/Therapist

There are many inhalation devices currently available to be prescribed for use, and great variability in devices approved for use in different parts of the world. Well-developed national and local guidelines and training programs for health professionals are important in ensuring that patients are prescribed the best available devices and formulations for their ages and disease conditions, and trained adequately in their optimal use. Despite training, surveys have shown diverging practices between health care centers for using and testing efficacy for inhaled treatments.[113] This demonstrates the confusion that arises due to the lack of consistency concerning advice around inhaled treatment devices from trained therapists and prescribers.

## Role of the Parent

Lack of cooperation is to be expected in this young age group and poses the main problem to adequate aerosol delivery observed. While several techniques can be successfully used, the degree of success largely depends on the advice given to parent. Positive, understanding advice results in higher success rates, while a negative attitude on the part of the person giving advice can make failure a self-fulfilling prophecy. There is currently no reliable data on this important aspect of aerosol therapy; however, these issues may explain the relatively lower use of pMDI with spacers and higher use of nebulizers in some regions. Nebulizers are generally thought to be better tolerated by infants, but again, data in this area are sparse.

# Progress Toward the Ideal Delivery System

Future research into providing an ideal delivery system for use in infants and young children could take several approaches. For pMDI-based systems, the development of low emission velocity breath-actuated devices designed for use at lower inspiratory flows and lung volumes would be more suited for use in younger children than the current commercial breath-actuated devices. The more recent use of low or antistatic plastics, and better-designed valves resulting in improved drug delivery from small volume spacers could possibly lead to the future development of smaller, single unit pMDI-spacer devices that are more portable and easier to use.

Dry powder systems are being developed to achieve better deaggregation of the powder into fine particles at low air flows to allow slow inhalation of the powder. The advent of engineered particles such as PulmoSpheres (Novartis), which are hollow porous particles with low surface energy, has led to the development of DPIs that achieve good lung penetration and deposition at low inspiratory flows, as the low density of the large particles make them behave in a similar manner to smaller, more dense particles in an air flow.[114–116] Nonbreath driven DPI systems, which do not require the patient to achieve a given optimal inspiratory flow for effective use of the device, are also being developed.

A device that produces a continuous aerosol of dry powder in an airstream analogous to a nebulizer has been developed to deliver surfactant to premature infants[117] and has achieved concentrations of aerosolized surfactant of up to 12 g/m$^3$ at a flow of 0.84 L/min and particles sizes of 3–3.5 μm. It is designed as a platform for the administration of many drugs that require high total therapeutic doses with slow delivery rates.

A recently developed device, the tPAD (**t**rans-Nasal **P**ulmonary **A**erosol **D**elivery), has been shown to be suitable for administration of extra fine aerosols via a cannula and nasal prongs over extended periods, up to 8 hours, at low flows. A comparable dosage of hypertonic saline to the lungs to that from a conventional jet nebulizer was achieved in healthy subjects.[118] The hands-free design makes it suitable for administration of drugs to children, who can continue activities while receiving their medication, or potentially while sleeping.

Intrapulmonary generation of aerosols is one potential method to avoid the problems of low inspiratory flow rates and small breath volumes leading to poor drug deposition in the lungs of small children and infants. A device known as the Microjet has been developed, where the aerosol is generated at or near to the target site, by intrapulmonary aerosolization within an endotracheal tube.[100] This instrument is designed to administer aerosolized surfactant to infants with respiratory distress syndrome.

# Physical Therapies in Pediatric Respiratory Disease

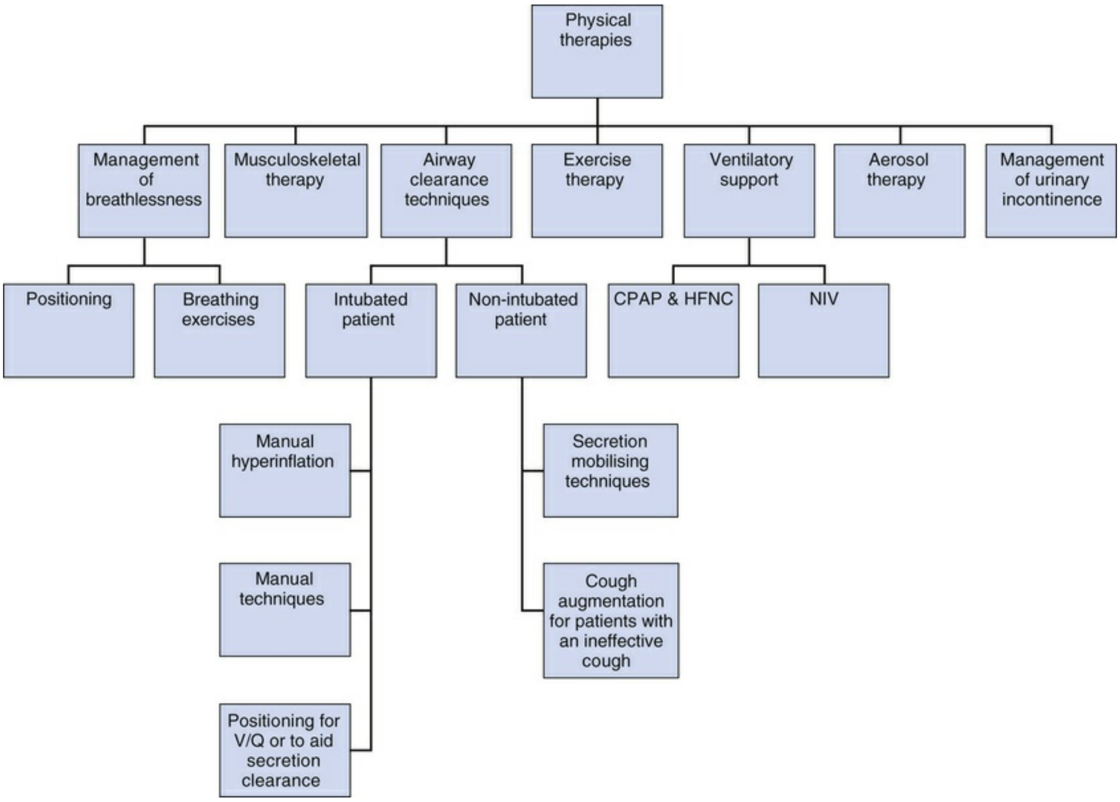
*Sarah Wright Grad Dip Phys, Ruth Wakeman MSc, BSc (Hons), Nicola Collins BSc (Hons), Michelle Chatwin BSc (Hons), PhD*

Pediatric cardiorespiratory physical therapy (physiotherapy) management spans the spectrum of care from specialist advice to nonpharmacologic interventions for patients with a variety of respiratory conditions. Physiotherapists are an essential part of the multidisciplinary team and physiotherapy is administered from birth to the time of transition to adult services across the continuum of care settings. To provide optimal care, the therapist will clearly identify the indicators for intervention and balance these against the possible risks. Physiotherapy is not a prescribed procedure; the frequency and dosage of therapy is continually adapted and modified in response to identified outcomes and targeted goals.[1,2]

Treating children can be difficult, and the physiotherapist must be responsive to individual needs and have the technical and nontechnical knowledge, skills and attributes to meet these challenges.

## General Principles of Physiotherapy

Physiotherapy often focuses on treating or alleviating generic problems that are amenable to intervention rather than being disease-specific (Fig. 17.1). In some instances, however, interventions are selected based upon the underlying disease process (e.g., primary ciliary dyskinesia [PCD] versus cystic fibrosis [CF]), whereby the elements of the mucociliary escalator affected by the disease process may differ (predominantly ciliary dysfunction versus altered sputum rheology). The pediatric respiratory physiotherapist/therapist will perform a wide variety of roles. The professionals and their training vary internationally. In the United Kingdom, physiotherapists are able to treat patients without a referral from a medical doctor and are therefore independent practitioners. Prior to pediatric physiotherapy, informed consent from caregivers and age-appropriate assent from the child are obtained.



Physical therapies
Management of breathlessness
Musculoskeletal therapy
Airway clearance techniques
Exercise therapy
Ventilatory support
Aerosol therapy
Management of urinary incontinence
Positioning
Breathing exercises
Intubated patient
Non-intubated patient
CPAP & HFNC
NIV
Manual hyperinflation
Secretion mobilising techniques
Manual techniques
Cough augmentation for patients with an ineffective cough
Positioning for V/Q or to aid secretion clearance

**FIG. 17.1** The physical therapies that can be offered to a child with respiratory disease are shown. *CPAP,* Continuous positive airway pressure; *NIV,* noninvasive ventilation; *V/Q,* ventilation perfusion.

The respiratory physiotherapist/therapist needs physiologic knowledge and practical skills to perform a competent respiratory assessment of the child. From this assessment, problems responsive to physiotherapy are identified and treatment strategies are recommended and implemented. Physiotherapists may also assess the reaction to inhaled pharmacologic agents (e.g., bronchodilator response and nebulized antimicrobial bronchoconstriction trials; Chapter 16), provide education in inhaler and nebulizer techniques, and advise on the optimal timing of inhaled medications with respect to sessions of respiratory physiotherapy. They can also assess the need for home oxygen therapy by performing exercise testing with oximetry.[3] Physiotherapists may also help to identify potential causes of respiratory problems (e.g., gastroesophageal reflux [GER] during airway clearance). These issues can then be escalated to be reevaluated by the medical team. If it is felt that pulmonary secretions are a result of aspiration secondary to uncoordinated swallowing, a speech and language assessment is warranted (see section "Aerodigestive Disease").

The timing of physiotherapy treatments can be important; for example, airway clearance should be timed before feeds or delayed for a sufficient time after feeds to avoid vomiting and aspiration. Likewise, physiotherapy should be timed around analgesia when clinically necessary.

## Role of Physiotherapy in Pediatric Respiratory Disease

Physical therapies are essential in the removal of excess bronchopulmonary secretions and maintaining and improving exercise capacity. Physical therapy can support ventilation using high-flow nasal cannulas (HFNCs), continuous positive airway pressure (CPAP) or noninvasive ventilation (NIV). Physical therapy should include postural education where appropriate; it can be used to prevent, correct, or improve postural problems, such as kyphosis in CF patients (Fig. 17.2). Postural education can also be helpful in musculoskeletal dysfunction, in children with contractures that inhibit function, or in children with pain that limits range of motion, mobility, and ability to breathe normally. Poor posture leads to tightening of the respiratory muscles, which can lead to chest wall deformity and contribute to a decline in pulmonary function. It is therefore essential that patients with chronic lung disease have a postural assessment and treatment of any musculoskeletal disorders identified, including core muscle imbalance.

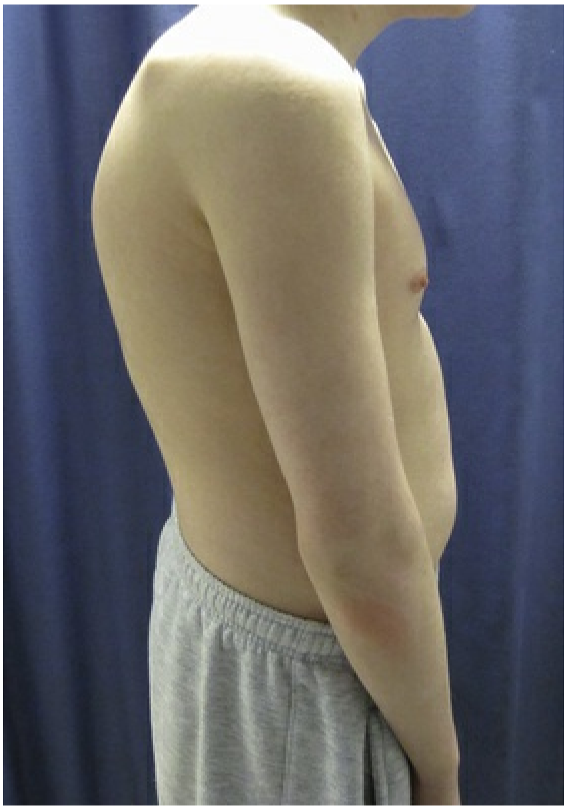


**FIG. 17.2** The onset of kyphosis in a male patient with cystic fibrosis.

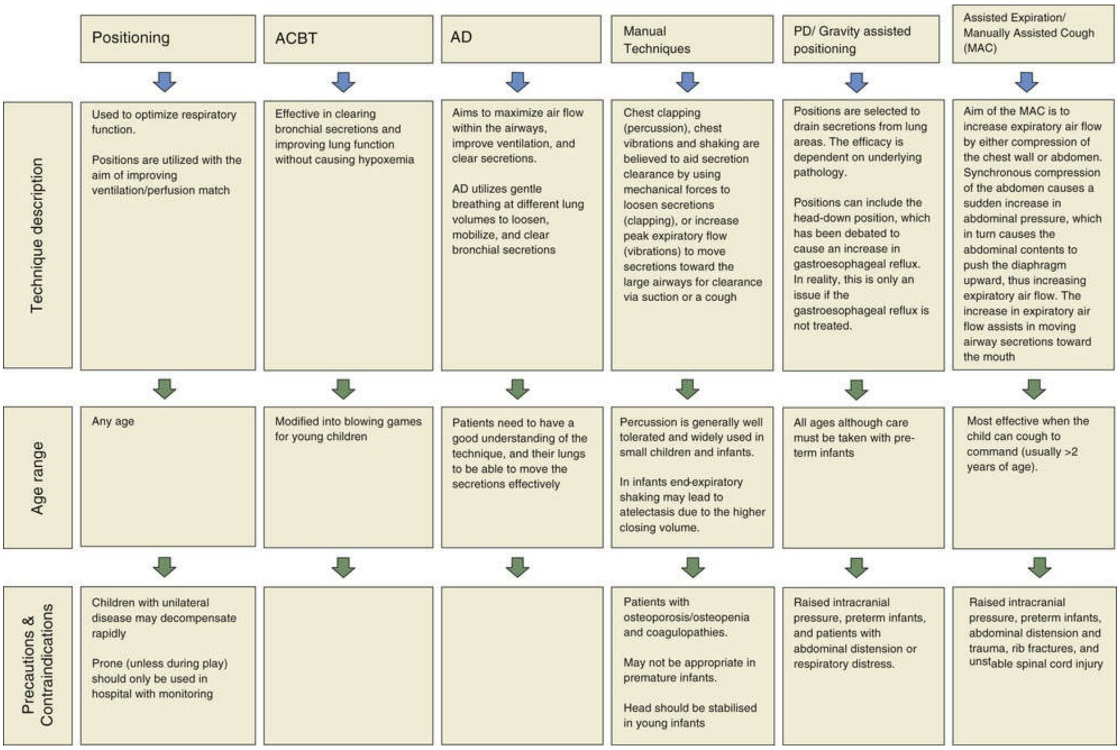
Specifically in neuromuscular disease (NMD), physical therapy is essential to maintain ambulation or facilitate standing, where possible, to improve lung function. Optimizing the maturing musculoskeletal and neuromuscular systems of a child with CF may play an important role in the long-term outcome of the child's mental and physical state.[4] It is essential to ask children with chronic lung disease about urinary and fecal incontinence in a private and empathetic setting; reluctance to cough may stem from fear of incontinence. Physical therapies should be directed toward managing this problem.[5,6]

# Respiratory Physiotherapy in Specific Conditions

## Cystic Fibrosis and Noncystic Fibrosis Bronchiectasis (Including Primary Ciliary Dyskinesia)

### Airway Clearance

Treatment options for airway clearance depend on the child's age and ability to participate in treatment. There is a wide variety of airway clearance techniques (ACTs; Figs. 17.3–17.5). There is no single best technique, so the therapist should not assume that the findings all apply to non-CF bronchiectasis.[2,7–12]

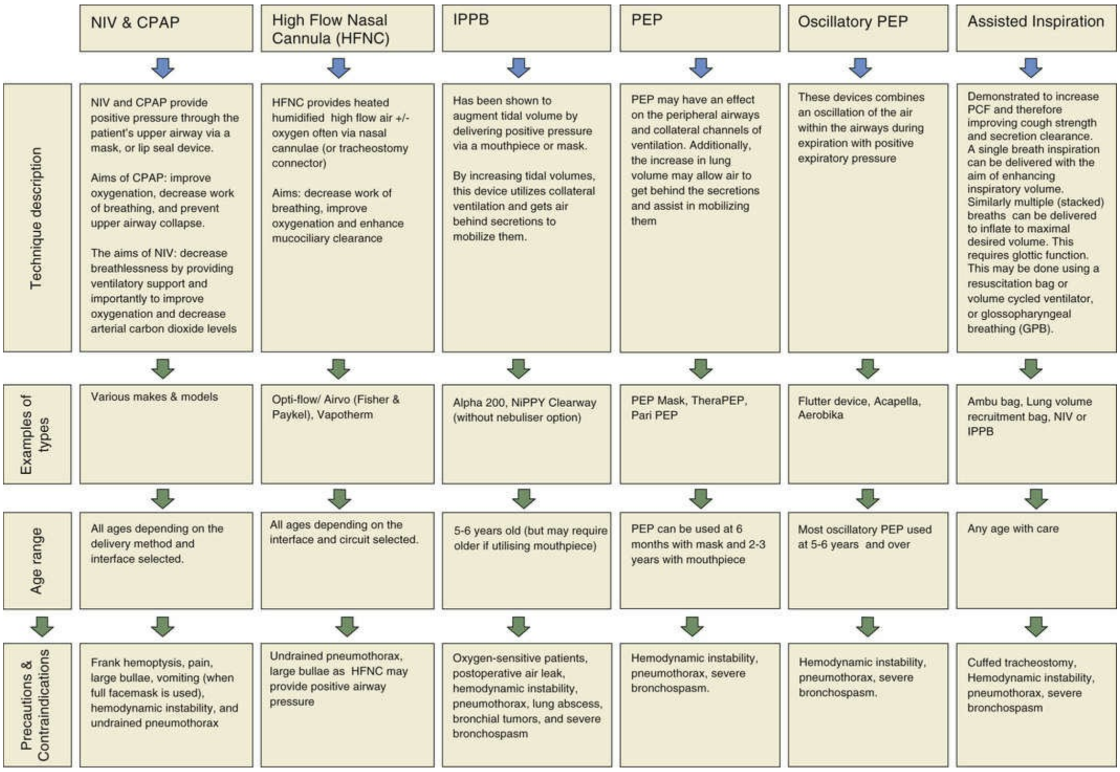


| | Positioning | ACBT | AD | Manual Techniques | PD/ Gravity assisted positioning | Assisted Expiration/ Manually Assisted Cough (MAC) |
|---|---|---|---|---|---|---|
| Technique description | Used to optimize respiratory function.<br>Positions are utilized with the aim of improving ventilation/perfusion match | Effective in clearing bronchial secretions and improving lung function without causing hypoxemia | Aims to maximize air flow within the airways, improve ventilation, and clear secretions.<br>AD utilizes gentle breathing at different lung volumes to loosen, mobilize, and clear bronchial secretions | Chest clapping (percussion), chest vibrations and shaking are believed to aid secretion clearance by using mechanical forces to loosen secretions (clapping), or increase peak expiratory flow (vibrations) to move secretions toward the large airways for clearance via suction or a cough | Positions are selected to drain secretions from lung areas. The efficacy is dependent on underlying pathology.<br>Positions can include the head-down position, which has been debated to cause an increase in gastroesophageal reflux. In reality, this is only an issue if the gastroesophageal reflux is not treated. | Aim of the MAC is to increase expiratory air flow by either compression of the chest wall or abdomen. Synchronous compression of the abdomen causes a sudden increase in abdominal pressure, which in turn causes the abdominal contents to push the diaphragm upward, thus increasing expiratory air flow. The increase in expiratory air flow assists in moving airway secretions toward the mouth |
| Age range | Any age | Modified into blowing games for young children | Patients need to have a good understanding of the technique, and their lungs to be able to move the secretions effectively | Percussion is generally well tolerated and widely used in small children and infants.<br>In infants end-expiratory shaking may lead to atelectasis due to the higher closing volume. | All ages although care must be taken with pre-term infants | Most effective when the child can cough to command (usually >2 years of age). |
| Precautions & Contraindications | Children with unilateral disease may decompensate rapidly<br>Prone (unless during play) should only be used in hospital with monitoring | | | Patients with osteoporosis/osteopenia and coagulopathies.<br>May not be appropriate in premature infants.<br>Head should be stabilised in young infants | Raised intracranial pressure, preterm infants, and patients with abdominal distension or respiratory distress. | Raised intracranial pressure, preterm infants, abdominal distension and trauma, rib fractures, and unstable spinal cord injury |

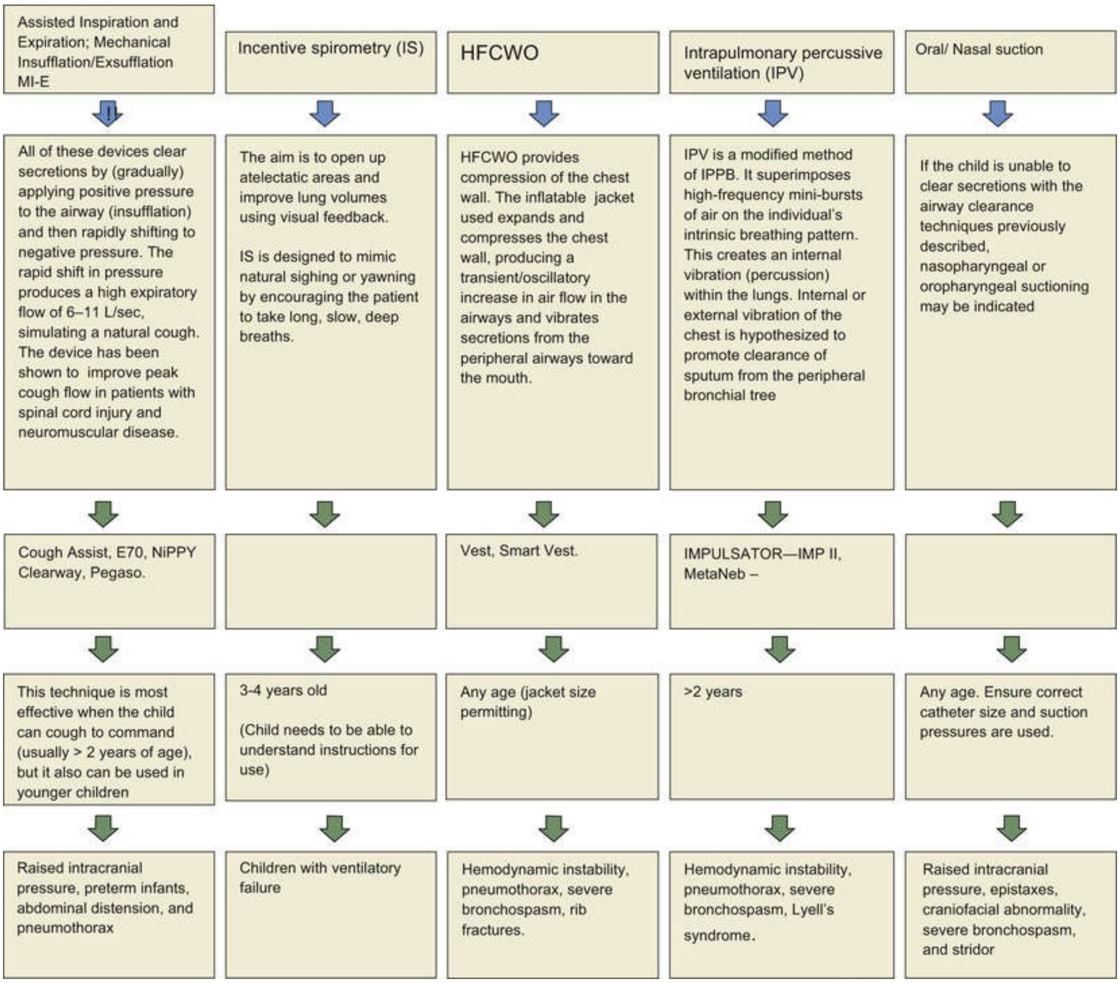
**FIG. 17.3** Airway clearance techniques requiring no equipment. Active cycle of breathing techniques: The technique consists of (1) breathing control (BC), which is a resting period of gentle relaxed breathing at the patient's own rate and depth; (2) thoracic expansion exercises, which are 3–5 deep breaths emphasizing inspiration; and (3) forced expiration technique (or

“huff”), which combines 1–2 forced expirations followed by a period of BC. The technique is flexible and can be performed in any position. Autogenic drainage (AD): The patient breathes in and holds his or her breath for 2–4 seconds (the hold facilitates equal filling of the lung segments). Expiration is performed keeping the upper airways open (as if sighing). The expiratory force is balanced so that the expiratory flow reaches the highest rate possible without causing airway compression. This cycle is repeated at different lung volumes while collecting secretions from the peripheral airways and moving them toward the mouth. Intermittent positive pressure breathing: Makes include Alpha 200 (Air Liquide Medical Systems, France), NiPPY Clearway (B&D Electromedical, Warwickshire, United Kingdom). Positive expiratory pressure (PEP): Usually PEP consists of a mask with a one-way valve to which expiratory resistance is added. A manometer is inserted into the circuit between the valve and resistance to monitor the pressure, which should be 10–20 cm $H_2O$ during midexpiration. The child usually sits with his or her elbows on a table and breathes through the mask for 6–10 breaths with a slightly active expiration. Makes include PEP Mask (Astratech, Stonehouse, Gloucestershire, United Kingdom), TheraPEP (Smiths Medical, Watford, United Kingdom), Pari PEP (PARI GmbH, Germany). Oscillatory PEP: Positions during use may vary slightly depending on the device type. Often patients will perform 4–8 deep breaths followed by a forced expiration. Makes include the Flutter device (Clement Clarke International Limited, Harlow, Essex, United Kingdom), the Acapella (Henleys Medical, Welwyn Garden City, Hertfordshire, United Kingdom), Aerobika (Trudell Medical Int, Canada). Mechanical insufflation/exsufflation (MI-E): The weaker the child the higher the requirement will be for high insufflation and exsufflation pressures. In children, an insufflation time of less than 1 second is required for equilibration of insufflation pressure and alveolar pressure. Longer exsufflation times do not significantly alter expiratory flows. Higher insufflation and exsufflation pressures both increase expiratory flows, but greater exsufflation pressure had more substantial impact on expiratory flows (1) Cough Assist

(Philips Respironics, Andover, Massachusetts) NiPPY Clearway, Pegaso (Dimla-Italia, Bologna, Italy); HFCWO—Makes include Vest (Hill-Rom, St Paul, Minnesota) or Smart Vest (Electromed, New Prague, Minnesota); Intrapulmonary percussive ventilation—Makes include IMPULSATOR—F00012, IPV1C—F00001-C, IPV2C—F00002-C. (Percussionaire Corporation, United States of America), IMP II (Breas, Sweden), Metaneb (Hill-ROM St. Paul, Minnesota). Manual hyperinflation: Patients receive normal tidal volumes coupled with an increased tidal volume using a 500-mL infant bag (or a 1-L bag for older children). A manometer is applied to the circuit to monitor pressures. As a general guide, manual hyperinflation ventilation pressures should not exceed 10 cm $H_2O$ above the ventilator pressure. Flow rates of gas should be adjusted according to the child: 4 L/min for infants, increasing to 8 L/min for children. (From Striegl AM, Redding GJ, Diblasi R, Crotwell D, Salyer J, Carter ER. Use of a lung model to assess mechanical in-exsufflator therapy in infants with tracheostomy. *Pediatr Pulmonol*. 2011;46(3):211-217.)



| | NIV & CPAP | High Flow Nasal Cannula (HFNC) | IPPB | PEP | Oscillatory PEP | Assisted Inspiration |
|---|---|---|---|---|---|---|
| Technique description | NIV and CPAP provide positive pressure through the patient's upper airway via a mask, or lip seal device.<br>Aims of CPAP: improve oxygenation, decrease work of breathing, and prevent upper airway collapse.<br>The aims of NIV: decrease breathlessness by providing ventilatory support and importantly to improve oxygenation and decrease arterial carbon dioxide levels | HFNC provides heated humidified high flow air +/- oxygen often via nasal cannulae (or tracheostomy connector)<br>Aims: decrease work of breathing, improve oxygenation and enhance mucociliary clearance | Has been shown to augment tidal volume by delivering positive pressure via a mouthpiece or mask.<br>By increasing tidal volumes, this device utilizes collateral ventilation and gets air behind secretions to mobilize them. | PEP may have an effect on the peripheral airways and collateral channels of ventilation. Additionally, the increase in lung volume may allow air to get behind the secretions and assist in mobilizing them | These devices combines an oscillation of the air within the airways during expiration with positive expiratory pressure | Demonstrated to increase PCF and therefore improving cough strength and secretion clearance. A single breath inspiration can be delivered with the aim of enhancing inspiratory volume. Similarly multiple (stacked) breaths can be delivered to inflate to maximal desired volume. This requires glottic function. This may be done using a resuscitation bag or volume cycled ventilator, or glossopharyngeal breathing (GPB). |
| Examples of types | Various makes & models | Opti-flow/ Airvo (Fisher & Paykel), Vapotherm | Alpha 200, NiPPY Clearway (without nebuliser option) | PEP Mask, TheraPEP, Pari PEP | Flutter device, Acapella, Aerobika | Ambu bag, Lung volume recruitment bag, NIV or IPPB |
| Age range | All ages depending on the delivery method and interface selected. | All ages depending on the interface and circuit selected. | 5-6 years old (but may require older if utilising mouthpiece) | PEP can be used at 6 months with mask and 2-3 years with mouthpiece | Most oscillatory PEP used at 5-6 years and over | Any age with care |
| Precautions & Contraindications | Frank hemoptysis, pain, large bullae, vomiting (when full facemask is used), hemodynamic instability, and undrained pneumothorax | Undrained pneumothorax, large bullae as HFNC may provide positive airway pressure | Oxygen-sensitive patients, postoperative air leak, hemodynamic instability, pneumothorax, lung abscess, bronchial tumors, and severe bronchospasm | Hemodynamic instability, pneumothorax, severe bronchospasm. | Hemodynamic instability, pneumothorax, severe bronchospasm. | Cuffed tracheostomy, Hemodynamic instability, pneumothorax, severe bronchospasm |



| Assisted Inspiration and Expiration; Mechanical Insufflation/Exsufflation MI-E | Incentive spirometry (IS) | HFCWO | Intrapulmonary percussive ventilation (IPV) | Oral/ Nasal suction |
|---|---|---|---|---|
| All of these devices clear secretions by (gradually) applying positive pressure to the airway (insufflation) and then rapidly shifting to negative pressure. The rapid shift in pressure produces a high expiratory flow of 6–11 L/sec, simulating a natural cough. The device has been shown to improve peak cough flow in patients with spinal cord injury and neuromuscular disease. | The aim is to open up atelectatic areas and improve lung volumes using visual feedback.<br>IS is designed to mimic natural sighing or yawning by encouraging the patient to take long, slow, deep breaths. | HFCWO provides compression of the chest wall. The inflatable jacket used expands and compresses the chest wall, producing a transient/oscillatory increase in air flow in the airways and vibrates secretions from the peripheral airways toward the mouth. | IPV is a modified method of IPPB. It superimposes high-frequency mini-bursts of air on the individual's intrinsic breathing pattern. This creates an internal vibration (percussion) within the lungs. Internal or external vibration of the chest is hypothesized to promote clearance of sputum from the peripheral bronchial tree | If the child is unable to clear secretions with the airway clearance techniques previously described, nasopharyngeal or oropharyngeal suctioning may be indicated |
| Cough Assist, E70, NiPPY Clearway, Pegaso. | | Vest, Smart Vest. | IMPULSATOR—IMP II, MetaNeb – | |
| This technique is most effective when the child can cough to command (usually > 2 years of age), but it also can be used in younger children | 3-4 years old<br>(Child needs to be able to understand instructions for use) | Any age (jacket size permitting) | >2 years | Any age. Ensure correct catheter size and suction pressures are used. |
| Raised intracranial pressure, preterm infants, abdominal distension, and pneumothorax | Children with ventilatory failure | Hemodynamic instability, pneumothorax, severe bronchospasm, rib fractures. | Hemodynamic instability, pneumothorax, severe bronchospasm, Lyell's syndrome. | Raised intracranial pressure, epistaxes, craniofacial abnormality, severe bronchospasm, and stridor |

**FIG. 17.4** Airway clearance techniques requiring equipment. Airway clearance techniques: The technique consists of (1) breathing control (BC), which is a resting period of gentle relaxed breathing at the patient's own rate and depth; (2) thoracic expansion exercises, which are 3–5 deep breaths emphasizing inspiration; and (3) forced expiration technique (or “huff”), which combines 1–2 forced expirations followed by a period of BC. The technique should be tailored to the individual, and choice is dependent on efficacy, simplicity of use, and cost.[1,2] A good starting point is with the technique that is simplest to use and that impinges least on the patient's life.[13] The term *airway clearance* describes a number of different treatment modalities that aim to enhance the clearance of bronchopulmonary secretions.[14] Through clinical reasoning, the therapist decides the aim of treatment and how to address the specific issue (or issues). Lannefors and colleagues clearly identified the following four stages of airway clearance; they are the cornerstones to decision making.[15]

1. To get air behind mucus so as to open up the airways
2. To loosen/unstick the secretions from the small airways (Video 17.1)
3. To mobilize the secretions through the smaller airways to the larger airways
4. To clear the secretions from the central airways

The age and adherence of the individual and caregivers as well as disease severity will affect the modalities introduced and in what combination. In the infant, manual techniques[16] (Figs. 17.6–17.8), positioning,[17] infant positive expiratory pressure (PEP[18]; Fig. 17.9), and assisted autogenic drainage (AAD)[19] are used. PEP and AAD focus on enhancing changes in air flow and ensuring the move from "passive" techniques to a more dynamic approach. The use of movement is encouraged from an early age, as it is not only more effective but also more realistic in the younger age group (Video 17.2▶).

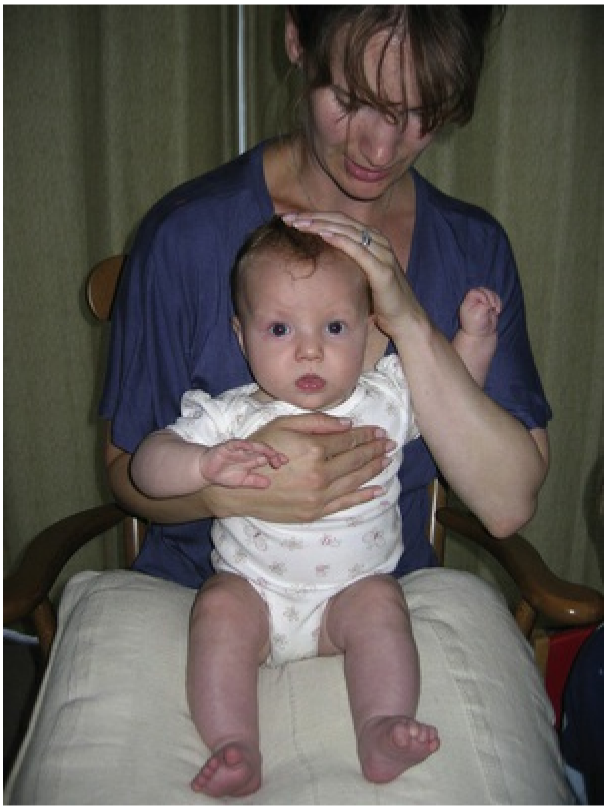

**FIG. 17.6** Percussion to the anterior chest for an infant with cystic fibrosis.

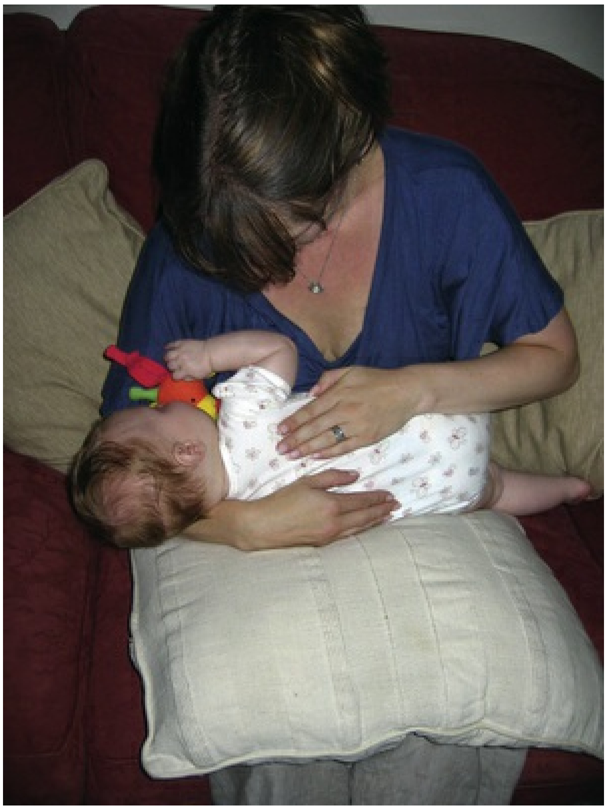

**FIG. 17.7** Infant with cystic fibrosis in side-lying position for physiotherapy.

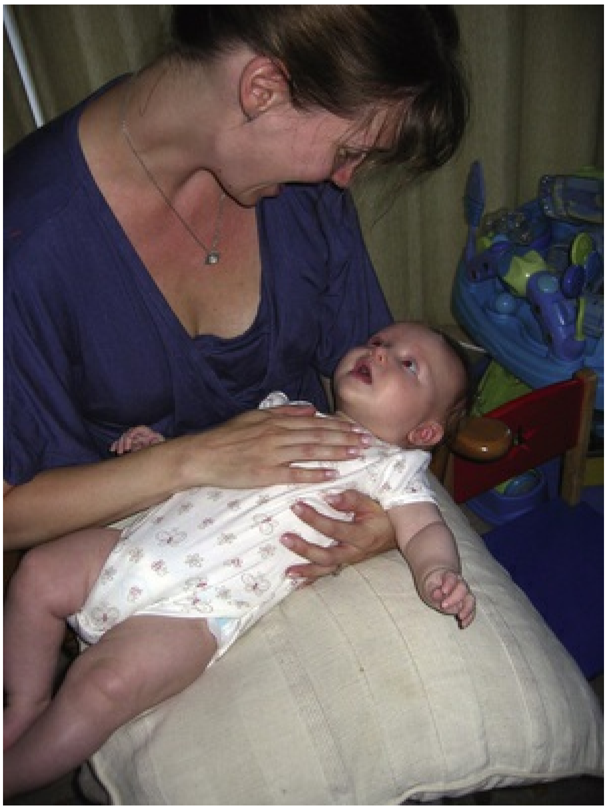

**FIG. 17.8** Infant with cystic fibrosis in supine position for physiotherapy.

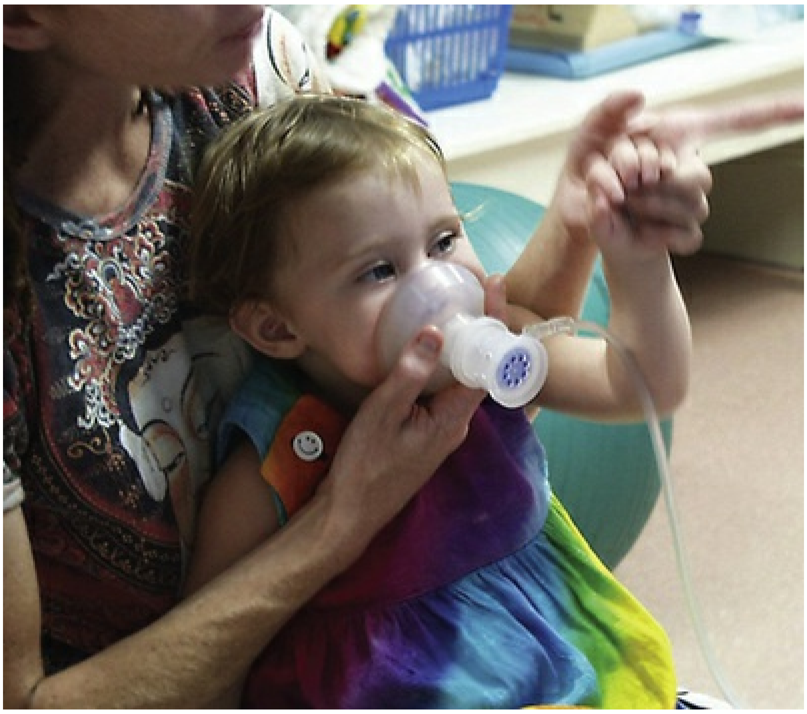

**FIG. 17.9** Toddler with cystic fibrosis using mask positive expiratory pressure.

As the child grows older and can become an active participant in therapy, the emphasis will change. The therapist can incorporate techniques that augment volume and introduce the concept of a change in expiratory flow; in many cases, this is a forced expiration.[20] Forced expiration or "huffing" is integral to many techniques and utilizes the theory of the equal pressure point to move mucus to the larger airways.[21] It is also a valuable assessment tool for children, as chest palpation during a "huff" can often be abnormal, with crackles being palpable, even when there are no abnormalities on auscultation. In young children, forced expiration will start as blowing games and then become a more formal component of ACT.

With the child's increasing ability to participate, the active cycle of breathing techniques (ACBT[17,22]; Fig. 17.10) can be taught and may be used in postural drainage (PD) positions (see Figs. 17.3–17.5). Physiotherapy may consist of modified PD targeting the area of lung affected or rotating through different areas to ensure that the lung fields are clear.[16] Other techniques such as autogenic drainage (AD; Fig. 17.11) also can be considered.[23] In addition, many adjuncts are available, with PEP (Figs. 17.12 and 17.13)[24] or oscillatory PEP (Figs. 17.14 and 17.15)[25,26] commonly used to facilitate clearance and to help move the child toward independence if appropriate. PEP has been shown to reduce exacerbations significantly more than other ACTs.[12] However, different physiotherapy techniques and devices may be more or less effective at varying times (e.g., stable state and during an exacerbation) and in different individuals. CF registry data from 2011 found that oscillating PEP and "huffing" were the most commonly used techniques in the United Kingdom and that PD and high-frequency chest wall oscillation (HFCWO; Fig. 17.16) were the least common.[27] Several of these adjuncts can be used in combination with inhaled medications (e.g., hypertonic saline; Fig. 17.17) or in conjunction with exercise.

HFCWO (see Figs. 17.3–17.5) is widely used across North America. Although evidence indicates that it may be less effective than other therapies,[28,29] including one study showing significantly greater pulmonary exacerbations in patients using HFCWO compared with PEP,[30] it can still be considered for specific individuals or used in combination with other ACTs. One other device that may be of benefit is intrapulmonary percussive ventilation (IPV; Fig. 17.18 and 17.19). Previous studies have investigated sputum mobilization in CF patients by comparing the use of IPV to other modes of airway clearance (e.g., PD and percussion, HFCWO, and oscillatory PEP).[31–33] These studies have shown IPV to be as effective as the other methods of airway clearance in sputum mobilization.

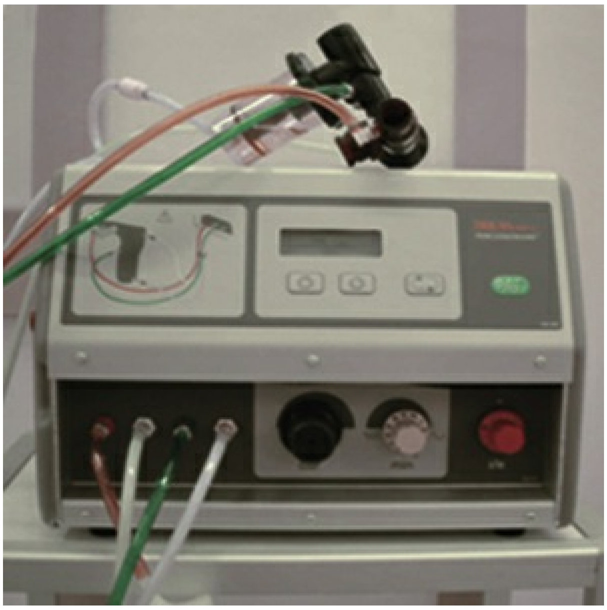

**FIG. 17.18** Intrapulmonary percussive ventilation.

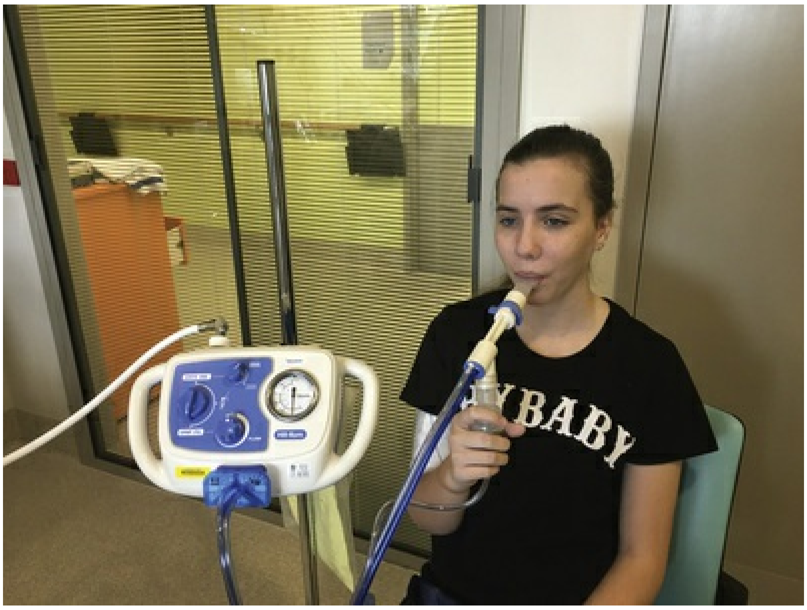

**FIG. 17.19** The MetaNeb® System (Hill-ROM, St. Paul, Minnesota).

Exercise has many benefits for people with CF and bronchiectasis: improving cardiovascular fitness, bone mineral density, and quality of life (Fig. 17.20). In CF it has been shown to slow the rate of pulmonary function decline[34] and may increase survival independent of $FEV_1$.[35] Exercise has also been shown to have an additive effect on sputum production, and it improves oxygen saturation in adolescents and adults with CF when used before airway clearance.[36] In fact, Dwyer and coworkers[37] have shown that exercising on a treadmill increases expiratory air flow and moves sputum from peripheral lung regions, but this must be combined with "huffing" to be an effective method of airway clearance.

**FIG. 17.20** Teenager with cystic fibrosis exercising on a "trampet."

Regular review of ACT is advised to ensure continuing effectiveness and adherence with therapy; appropriate adjustments to treatment can be made as necessary.[38,39] It is vital to monitor adherence, as, for example, poor adherence in bronchiectasis has been shown to affect important health outcomes including pulmonary exacerbations.[40] The most effective technique may not be the optimal strategy for the individual; multiple contributing factors must be considered. The regimen must be specific to each individual's changing needs and preferences, and as patients grow older, their understanding of the need for the treatment and of its goals must be clear. ACTs have been shown to have short-term effects on mucus transport, but the long-term effects are less clear.[41] There is debate worldwide regarding the introduction of ACT prior to diagnosis of bronchiectasis. There is consensus on the symptomatic patient, where response to treatment is evident; however, there is less agreement on the asymptomatic patient.[14] Chest physiotherapy does not have to be routinely performed unless the underlying diagnosis affects the normal mechanisms of airway clearance. In CF, there is evidence that inflammation, infection, abnormal lung function and ventilation inhomogeneity are present early in life.[42] In addition, for CF or PCD, it seems unethical to wait for airway damage to occur, as the child will thus never have normal mucociliary clearance.[43]

## Ventilatory Support

As the disease progresses, use of devices that provide some inspiratory ventilatory support may be the treatment of choice. The use of NIV has been shown to significantly improve ease of sputum clearance, reduce work of breathing,[44] facilitate inspiration and correct respiratory failure; it is widely used in the adult setting. It has also been shown to significantly increase $FEV_1$ and reduce fatigue in CF adults hospitalized with an acute exacerbation.[45] However, a review of its use in CF children[46] demonstrated a need for more evidence and protocols to identify indications for this age group.

## Inhalation Therapies

Effective treatment in this group of patients might have to be supported by inhaled therapies (Fig. 17.21) such as bronchodilators; mucoactive agents such as hypertonic saline, dry powder mannitol (Bronchitol, licensed for over 6 years in Australia and 18 years in Europe) and deoxyribonuclease (RhDNase); antimicrobials, and, where indicated, oxygen therapy.[47–49] The timing of inhalation therapy around airway clearance is important (Fig. 17.22). For example, bronchodilators and mucokinetics should be given before or during ACT to prepare the airways.[50] RhDNase can be administered before (minimum 30 minutes) or after ACT to suit the individual, although in children with well-preserved lung function

$FEF_{25}$ was improved if RhDNase was given prior to ACT.[51] If RhDNase is given before ACT, it should be a longer time interval than immediately before ACT; in children it may be given before bed.[52] Antimicrobials and inhaled steroids should be administered following ACT.

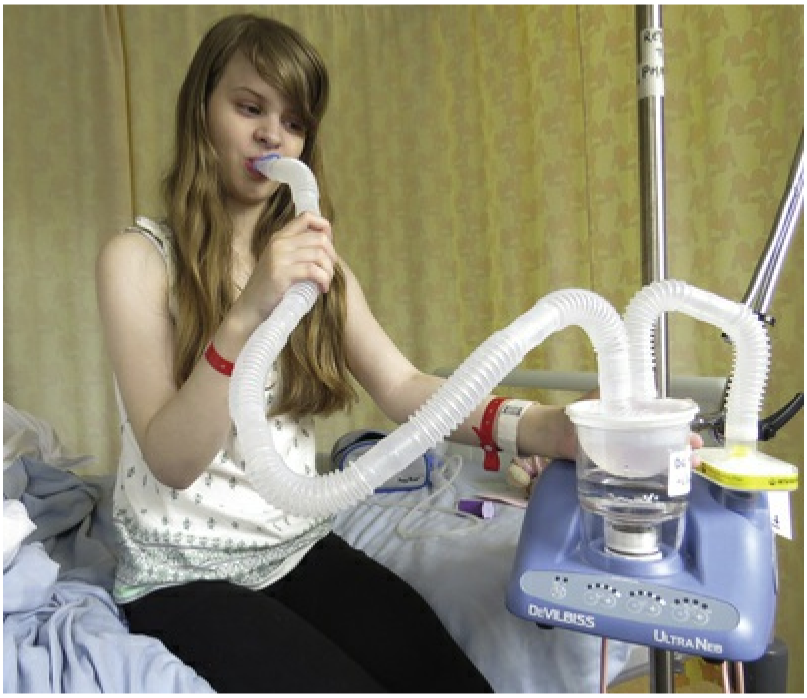

**FIG. 17.21** Girl with cystic fibrosis using ultrasonic nebulizer for saline inhalation.

## Complications and Implications for Physical Therapy

The relationship between ACT (particularly gravity-assisted positions) and GER remains unclear.[53,54] Physiotherapists must be aware of the possible risks with treatment and modify their therapies accordingly; thus the decision should not be on whether gravity will induce reflux but whether it is necessary to tip at all. Few therapists would tip a 4-week-old asymptomatic CF infant, but in a 1-year-old child with PCD that is at risk of developing acute large airway mucus impaction and lobar changes, PD may well form part of the treatment.

As mentioned, the impact of musculoskeletal issues including posture, incontinence,[55] and pain should be assessed and managed appropriately, including limiting muscle imbalance and strength training to improve the mechanics of breathing and overall well-being.[56] In addition, with the increasing longevity of patients and comorbidities such as diabetes, osteopenia will have to be considered by the therapist and management modified responsively. Often the combination of treatments can be beneficial; for example, ACT using PEP while the patient is on a therapy ball, utilizing core muscle strengthening can provide enhancements as well as reduce treatment time.

# Respiratory Muscle Weakness

## Neuromuscular Disease

The ability to clear bronchopulmonary secretions is essential to prevent sputum retention and associated complications, including lower respiratory tract infection. An effective cough is a vital mechanism to protect against respiratory tract infections, which are the commonest causes of hospital admission in patients with respiratory muscle weakness from NMD.[57] An intact afferent and efferent pathway is required for an effective cough. Reduced airway sensation will fail to elicit a cough in response to a noxious stimulus. Diseases of the nerves (upper or lower motor neuron), neuromuscular junction, or muscles may impair the efferent pathway.

The act of coughing involves the following three main components[58]:

1. Deep inspiration up to 85%–90% of total lung capacity
2. Glottic closure, which requires intact bulbar function so a rapid closure of the glottis occurs for approximately 0.2 seconds
3. Effective contraction of the expiratory muscles (abdominal and intercostal) to generate intrapleural pressures of more than 190 cm $H_2O$.

If one or more of these three components is impaired, the cough will be less effective[59] and the individual may be unable to produce the transient flow spikes essential for an effective cough (Fig. 17.23).[60] Cough strength can be measured by peak cough flow (PCF). PCF is the result of an explosive decompression that generates a flow rate as high as 360–944 L/min in children older than 12 years of age.[61] It is important not to quote adult PCF threshold values for children younger than 12 years of age and to use the appropriate quartile reference value.[61] Physical therapies involve the assessment of cough efficacy by formally evaluating the inspiratory, glottic and expiratory components of the cough along with audibility and measuring PCF with a peak flow meter attached to a face mask.

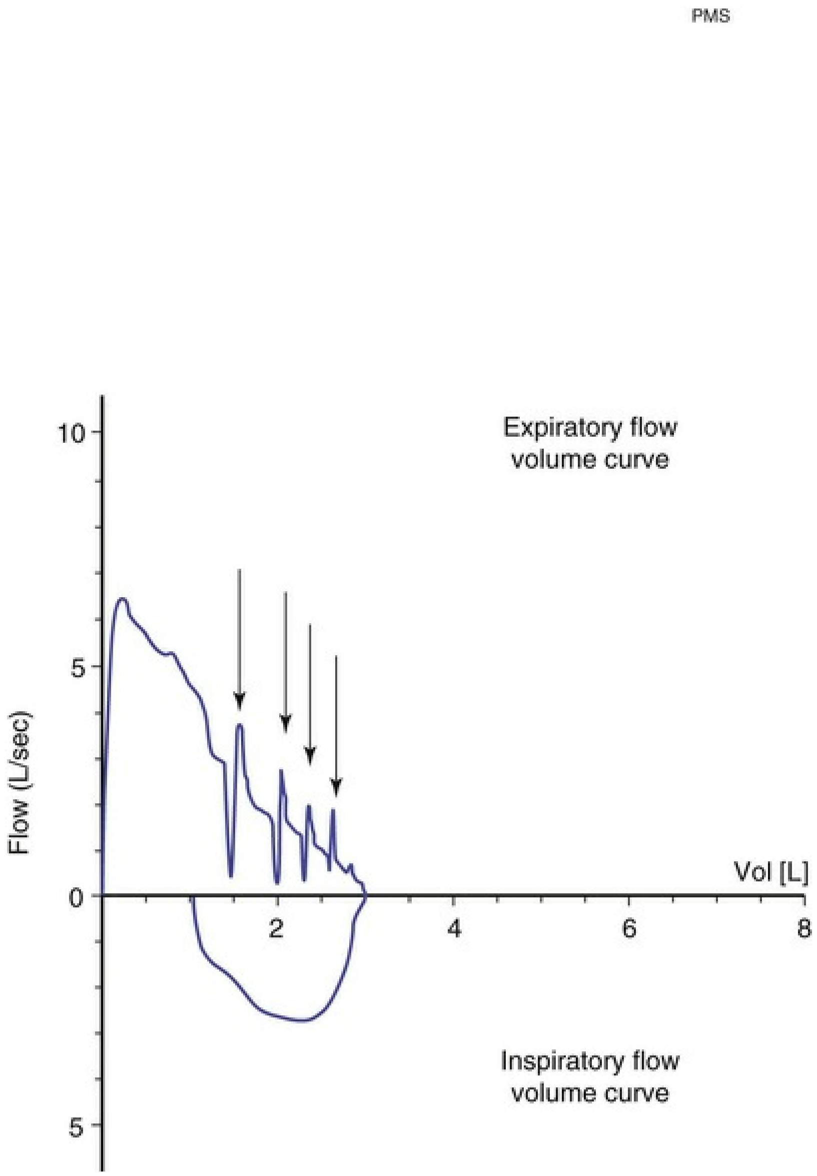

**FIG. 17.23** A series of cough spikes is superimposed on the maximal expiratory flow. Cough flow spikes are highlighted *(arrows).*

Poponick and coworkers[62] demonstrated that acute viral illness was associated with a reduction in vital capacity (VC) due to reduced inspiratory and expiratory respiratory muscle strength (by 10%–15% of baseline values). This reduction in inspiratory and expiratory muscle strength will also cause a decline in PCF, possibly to the critical level where the child is unable to clear secretions alone or with his or her normal assisted cough technique. Assisted cough techniques should be targeted to whichever component of the cough is reduced and may consist of assisted inspiration: single breaths (inspiration with expiration between) given with an Ambu bag or an intermittent positive pressure breathing (IPPB) device (Fig. 17.24).[63] They may also consist of stacked breaths (no breath out between inspirations) performed with an Ambu bag (Fig. 17.25), a lung volume recruitment bag, volume-cycled NIV,[64] or glossopharyngeal breathing (GPB).[65] Assisted cough techniques may also be applied during expiration, as with a manually assisted cough (Fig. 17.26; see also Figs. 17.3–17.5). If there is both inspiratory and expiratory muscle weakness, then a combination of assisted inspiration and expiration techniques should be utilized. These techniques have been shown to increase PCF either alone or in combination.[66–69]

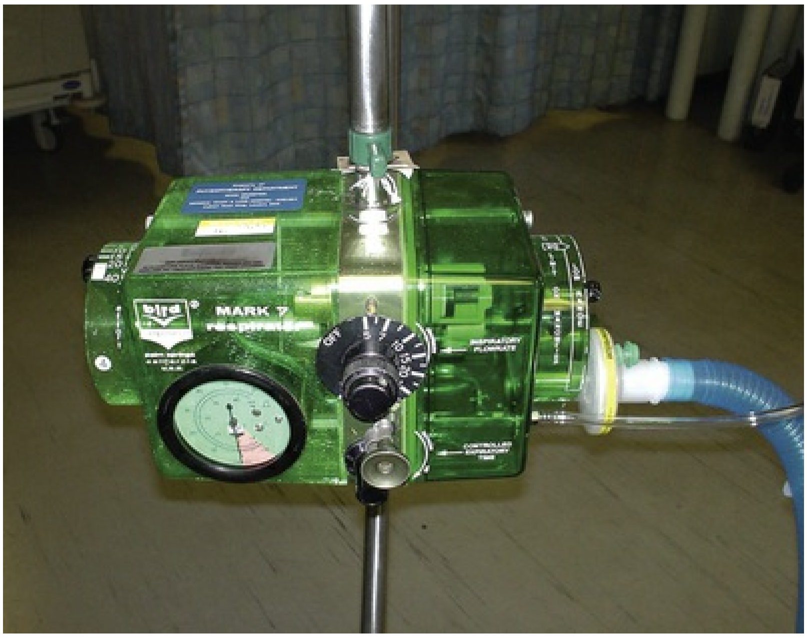

**FIG. 17.24** Intermittent positive pressure breathing device.

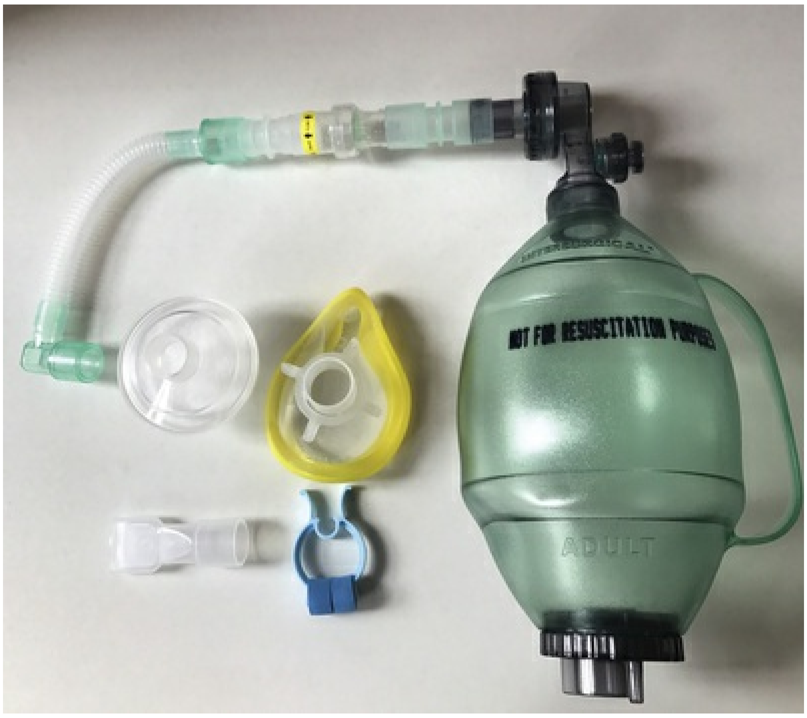

**FIG. 17.25** Lung volume recruitment bag (Intersurgical, Wokingham, England, UK) for the use in assisted inspirations.

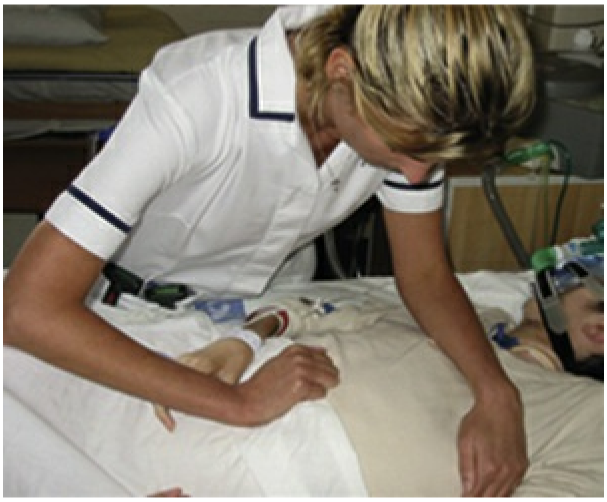

**FIG. 17.26** Manually assisted cough for a patient with neuromuscular disease.

If the cough is extremely impaired, the patient may require mechanical insufflation/exsufflation (MI-E) (Fig. 17.27).[70,71] This procedure clears secretions by gradually applying a positive pressure to the airway (insufflation) and then rapidly shifting to negative pressure (exsufflation). The rapid shift in pressure produces a high expiratory flow, simulating a natural cough. In pediatric patients with NMD, MI-E has been provided as part of a protocol in patients with a $PE_{max}$ of 20 cm $H_2O$ or less.[72] MI-E has also been shown to expedite secretion removal[73] and prevent intubation.[74] A combination of NIV and MI-E in spinal muscular atrophy type I has been associated with increased life expectancy when compared with the untreated natural history in observational studies.[75–78]

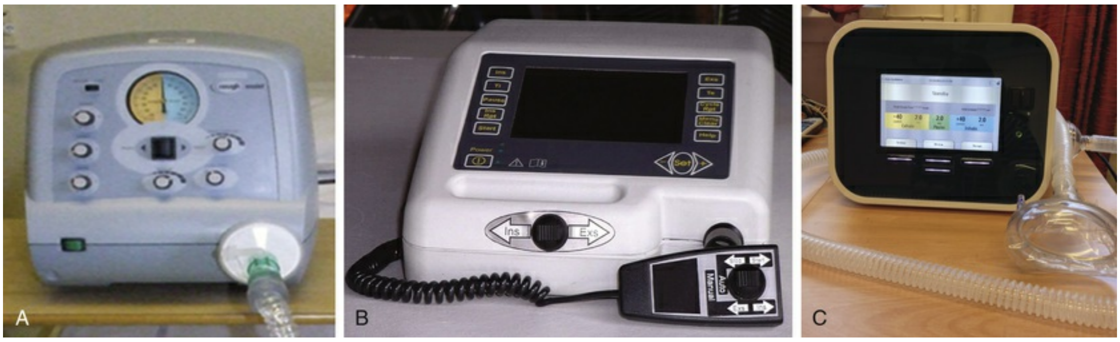

**FIG. 17.27** Cough assist device.

NIV (Fig. 17.28) may also have a role in preventing chest wall deformity in NMD.[78,79] Physical therapies that consist of secretion-mobilizing techniques in NMD may need to provide ventilator support. Such options include IPV (see Figs. 17.3–17.5),[80–82] a modified ACBT (adjusting the patients NIV settings), or HFCWO[83] on NIV where indicated (see Figs. 17.3–17.5). Patients who use NIV should not be taken off their ventilator for physiotherapy or transferred to CPAP. Some patients with NMD are provided with NIV to decrease their work of breathing and augment tidal volumes to enhance ACT. The ACBT can be modified by using NIV to provide deep breaths that mobilize secretions with or without manual techniques, followed by an assisted cough technique.

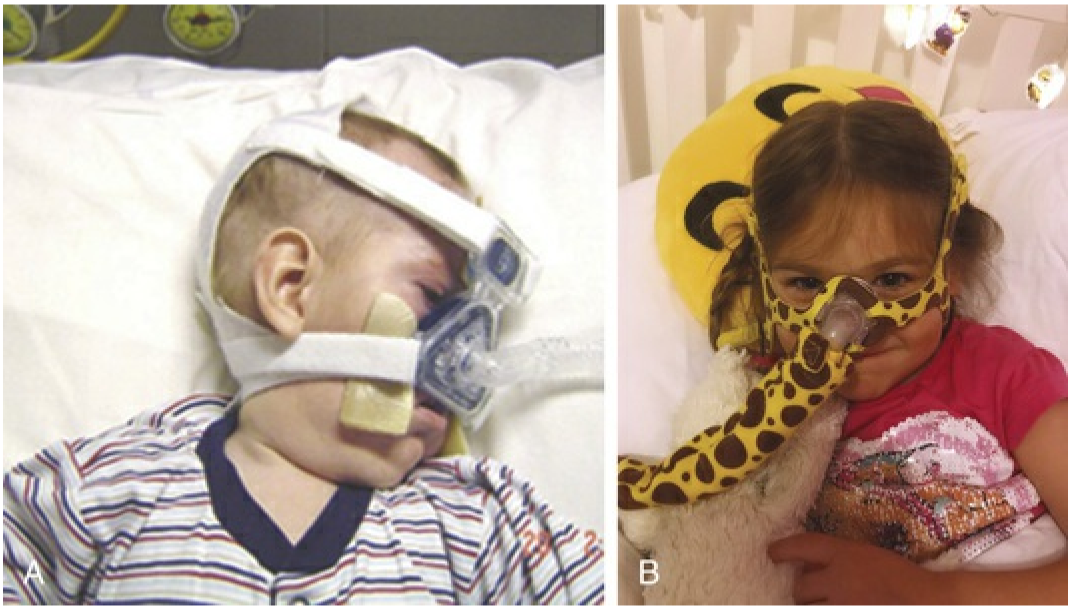

**FIG. 17.28** Child with noninvasive ventilation via nasal mask.

Outcome is improved when children with NMD are treated with an oximetry-driven protocol when they are unwell to avoid intubation or in preparation for extubation.[84] The protocol consists of carrying out cough augmentation techniques when the oxygen saturations decline below 95% on room air or on NIV without supplementary oxygen therapy. The rationale is that patients have atelectasis with secretion retention and treatment is required to reverse the process; this has been shown to increase survival in patients with NMD. Performing cough augmentation when the patient's oxygen saturation has declined below 95% has contributed to successful extubation and prevented the need for intubation in this patient group.[57,75,78,85]

Currently there is no evidence base for the use of respiratory muscle training in this patient group.[84]

## Spinal Cord Injury

Physical therapies should be appropriate to the level of the spinal cord injury. Cervical spinal cord injuries may require ventilator support in the form of NIV or, in higher spinal cord injuries, tracheostomy with intermittent positive pressure ventilation (TIPPV). Patients may need to be taught lung volume recruitment maneuvers in the form of assisted inspirations (see section "Neuromuscular Disease" and Figs. 17.3–17.5) to promote chest wall stretching,[86] along with lung growth and development. For injuries that included the thoracic spine, MAC should be taught (see Chapter 72 and Figs. 17.3–17.5).[87] Patients who are significantly weak are likely to benefit from MI-E either via a mask or tracheostomy; this has been reported to be less uncomfortable than suctioning.[88] Abdominal binders may also be required to minimize the effect of postural hypotension and aid in respiration.[89,90]

# Surgical and Critical Care

## Preoperative and Postoperative Management

Routine preoperative therapy is not indicated[91]; however, it may be desirable to teach physical therapies to high-risk children prior to surgery—for example, patients with coexisting respiratory conditions that may predispose to postoperative respiratory atelectasis and infection or patients with reduced mobility.

Exercise therapy is an essential part of postoperative care, and endurance training has a favorable influence on pulmonary function in patients after surgical correction of scoliosis.[92] Other postoperative physical therapies differ depending on the patient's status. Breathing exercises such as ACBT may be appropriate (or blowing games in younger children) if secretion retention is an issue. Incentive spirometry should not be used routinely[93] or if the child is mobilizing sufficiently; however, in isolated cases it can give visual feedback and encourage the child to take deeper breaths in an attempt to resolve atelectasis.[94] If there is a significant amount of atelectasis with a decline in oxygen saturation, a step up to HFNC,[95] CPAP or NIV may be necessary. IPPB (Bird Mark 7, Viasys Health Care, Bilthoven, The Netherlands)[96] may be of benefit for older children with sputum retention (see Fig. 17.24).[63,97]

## Critical Care

The physiotherapist is an integral part of the intensive care team, the indicators for intervention must be clearly defined and possible adverse events to these recognized. In the intubated child, ACTs are often used in combination for greater efficacy and appropriate anticipatory strategies put in place prior to treatment (e.g., preoxygenation, sedation). In addition to manual techniques and positioning, manual hyperinflation (MHI) may be indicated when areas of focal atelectasis or retained secretions are identified, with greater expiratory to inspiratory flow bias critical to the maneuver (Fig. 17.29, Video 17.3▶).[98] The roles of ventilator hyperinflations (VHIs) and the intrapercussive ventilator are currently under investigation.

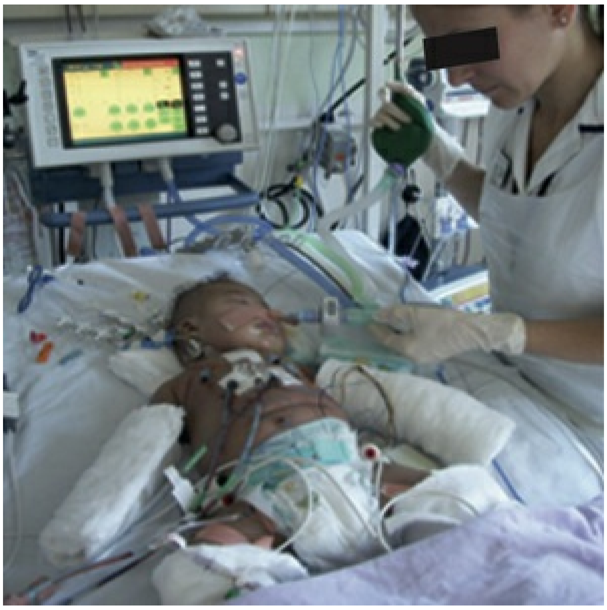

**FIG. 17.29** Physiotherapy (manual hyperinflation and manual techniques) being performed on a intubated and ventilated infant.

The focus in pediatric critical care is now directed toward early rehabilitation, even prior to extubation where possible (Fig. 17.30), as it has been shown to reduce ventilator days, length of stay and delirium and to increase muscle strength.[99] Recommendations in "at risk" adults also include the use of continuous passive motion (CPM) and electronic muscle simulation (EMS) daily (Fig. 17.31).[100] For some patients, inspiratory muscle training can facilitate weaning.[101] In the pediatric arena, there is evidence supporting a similar approach[102,103]; advocacy from the therapist is critical to overcome barriers and identify the children who would benefit.

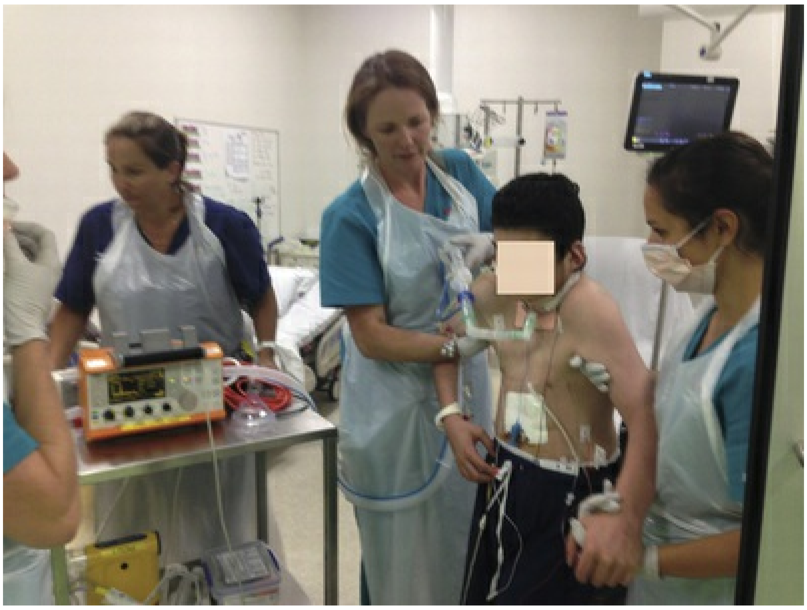

**FIG. 17.30** Mobilizing a young man on the intensive care while ventilated via a tracheostomy.

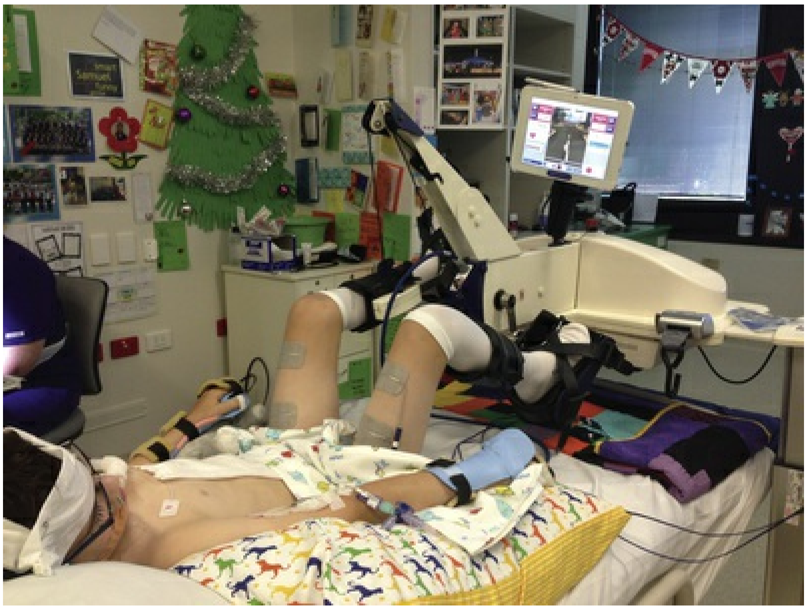

**FIG. 17.31** Functional electrical stimulation being used to assist rehabilitation for the lower limbs.

# Airway and Structural Disorders

## Asthma

A crucial part of physical therapy management of asthma is education of the child and parents, in particular the need for regular exercise when the child stable.[104] It is important to ensure ongoing adherence to prescribed medication (see Chapters 45 and 46). Physiotherapy includes advice on exercise that is specific to age and severity. In some children, breathing retraining using a reduced volume and/or frequency with relaxation can reduce symptoms and therefore improve quality of life. Several groups advocate specific techniques, but it is important to stress that these techniques are adjunctive to medication and are not replacement therapy. Routine airway clearance is rarely indicated in asthmatic patients, and it is important to remain aware that ACTs may exacerbate bronchospasm.

## Breathing Pattern Disorders

This is a particularly challenging area. It is important that the child undergo a full assessment prior to referral for physical therapies to rule out organic disorders (e.g., croup) and neurologic disorders (e.g., Rett syndrome). A careful history should be taken to investigate when symptoms are present. If the child is symptom-free during sleep, this may help to refine the diagnosis. If the child is suffering from a psychogenic disorder or other abnormal breathing patterns (e.g., hyperventilation syndrome and sighing dyspnea), then physiologic input will have benefit to identify triggers and provide advice on how to cope with them. Breathing reeducation is essential in this group of children and adolescents. Breathing retraining, which incorporates reduced respiratory rate and/or tidal volume, is a first-line treatment for hyperventilation syndrome with or without concurrent asthma. Identification of precipitating factors (e.g., sighing) and other triggers is important.

## Chest Wall Disorders

Physical therapies in chest wall disease are aimed at maximizing lung function. This includes pulmonary rehabilitation,[105] manual musculoskeletal therapies for postural pain, and initiation of NIV in the hypercapnic patient[106] along with postoperative rehabilitation after corrective surgery.

## Airway Structural Disorders

With the increased diagnosis of tracheomalacia and bronchomalacia via bronchoscopy, physiotherapists are building evidence for the use of PEP.[107] It is hypothesized that in children with some structural abnormalities, PEP can increase airway stabilization and enhance cough expiratory flow.[108] It is well known that children with airway malacia are prone to recurrent respiratory infections,[109] and further research is needed on the role of physiotherapy.

## Interstitial Lung Disease

There is little published evidence on physiotherapy for interstitial lung disease. Studies in adult patients have shown an improvement with exercise training in patients with this disease.[110–112] Adult patients with more advanced disease may benefit from ambulatory oxygen therapy and breathlessness management. Physical therapies for this condition include positioning to ease breathlessness. Given the very different spectrum of interstitial lung diseases in children (Fig. 17.32 and Section 6: Interstitial Lung Disease, of this book), recommendations based on adults should only be adopted with extreme caution and a detailed individualized assessment is essential.

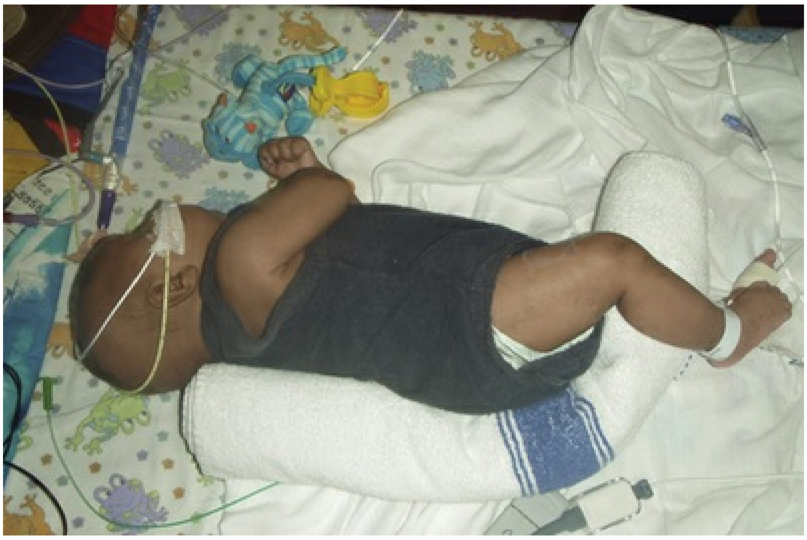

**FIG. 17.32** Positioning of an infant with chronic neonatal lung disease.

# Conditions Not Generally Amenable to Physiotherapy

## Acute Laryngotracheobronchitis (Croup)

Physical therapies are usually contraindicated in the spontaneously ventilating child with croup. However, other techniques may be indicated if the child is intubated and mechanically ventilated and secretions cannot be cleared by suction airway clearance alone.

## Pertussis

Any physical therapies during the acute phase of pertussis can precipitate paroxysmal cough and its complications. If the child is mechanically ventilated, paralyzed, and sedated and there are issues with retained secretions, ACTs may be of benefit (see Figs. 17.3–17.5). In the child with persistent lobar collapse and in whom the paroxysmal cough phase has ended, appropriate ACTs can be taught.

## Inhaled Foreign Body

Physical therapy is not indicated to remove the foreign body. These children require bronchoscopic removal of the material, usually with a rigid bronchoscope. After bronchoscopic removal, PD, manual techniques, and breathing exercises may be necessary to clear excess secretions that have accumulated in the obstructed airway behind the foreign body.

## Pulmonary Edema

ACTs are not indicated for pulmonary edema; however in some situations CPAP or NIV may be an appropriate strategy to help children with significant work of breathing while waiting for diuresis or other medical strategies to take effect.

## Lobar Pneumonia and Empyema

There is little evidence to support chest physiotherapy to treat lobar pneumonia[113,114] or empyema.[115] The pathophysiology of both conditions indicates that physiotherapy will not be effective in the acute stages or even during the resolution phase when secretions can appear in the airways; previously healthy children have the capability to clear these independently, with particular focus on mobilization. However, specific ACTs may be required in children with conditions that alter muscle tone (e.g., cerebral palsy), mobility/muscle strength (e.g., neuromuscular conditions), or mucociliary clearance (e.g., bronchiectasis).

## Bronchiolitis

Physical therapy is counterproductive during the acute stage of bronchiolitis. Mechanically ventilated infants will need careful assessment and may benefit from ACTs if there is retention of secretions. Chest physiotherapy has not been shown to reduce length of hospital stay, oxygen requirements or clinical severity score[116]; intervention should be based on specific focal signs or comorbidities. In these cases, physiotherapy may need to be modified to reduce the impact on the infant's work of breathing and should be continually reassessed.

In children with normal lung defense mechanisms and function, chest physiotherapy is very unlikely to be of benefit for acute respiratory disorders. However, lack of evidence does not mean that this should be extrapolated to all children. It is imperative that the therapist be able to assess the patient and liaise with the medical team regarding the necessity of intervention so that appropriate treatment is provided.[117]

# Summary

Physical therapy is well established as part of the management of many respiratory conditions, in particular for children requiring mechanical ventilation and those with chronic disorders such as bronchiectasis or neuromuscular conditions. Over the past few decades, the profession has evolved, and a wide variety of techniques and modalities is available with a growing evidence base. Fundamentally the key to effective physiotherapy is identifying the physiologic issue, deciding whether physiotherapy strategies can assist, and identifying outcomes that can be measured. The latter must include both positive and negative effects so the therapist can assess the risk and take an informed approach to patient care. Integral to all of this are the therapeutic skills required in communication and engagement with the child and family to ensure an optimal outcome in the ever-changing face of the presentation.

## Introduction

The increased skill and widespread application of antenatal ultrasound and more recently antenatal magnetic resonance imaging (MRI) not only has allowed precise early diagnosis of many congenital malformations, but also has brought new problems. UK National Screening Committee guidelines recommend that all women be offered a detailed fetal anomaly scan at around 20 weeks' gestation to confirm the gestational age and examine the fetal anatomy in detail according to standards dictated by the Fetal Anomaly Screening Programme.[1] Many parents are now faced with having to decide what to do for a baby affected by one of many different abnormalities, some of which would have previously escaped detection. The natural history of many of these malformations is unknown, and so health professionals can have difficulty offering accurate information to parents faced with the unexpected diagnosis of an abnormality in their baby. The diagnosis of fetal lung lesions is one good example. Early reports published in the 1980s described a poor outcome for fetuses with lung masses detected in the second trimester. However, these studies were biased by a high incidence of intervention, including termination of pregnancy. With increasing use of antenatal ultrasound and the detection of many less obvious lesions, it has become clear that, if conservative management is followed, many may disappear or regress considerably by term. Indeed, as we will demonstrate in this chapter, the outcome for such fetuses is generally very good, and the dilemma now is whether to pursue conservative or surgical management in an asymptomatic infant. Further confusion arises as to how these malformations should be described. The nomenclature of congenital lung disease was never very clear, with terms such as sequestrated segment, cystic adenomatoid malformation, hypoplastic lung, and malinosculation being used to describe abnormalities that often overlap. Now, however, they are used inconsistently before and after birth. For example, congenital cystic adenomatoid malformation (CCAM), subsequently renamed as congenital pulmonary airway malformation (CPAM),[2] is used by perinatologists to describe a lesion that may well disappear before birth, but is used postnatally to describe an abnormality that may require lobectomy. CPAMs may have a pulmonary arterial supply or be supplied like a sequestration from systemic arteries, and histologic features of these lesions may overlap. Furthermore, overlap lesions, containing features of two or even three pathological entities, are common.[3–5] MRI now delineates the blood supply of antenatal malformations with increasing precision, although the ability to acquire sophisticated images is not necessarily the best indication for so doing. New treatment options, such as fetal surgery and even fetal interventional bronchoscopy, and postnatal embolization of feeding vessels, are available; however, the exact place of novel interventions is unclear. A complete reappraisal of the diagnosis, investigation, and management of congenital lung disease is thus timely. A complete review of congenital lung disease might also include a few disorders that are acquired in utero, such as congenital pneumonias (discussed in Chapter 19), but this chapter is limited to the stricter definition of developmental disorders. There is overlap with the developmental components of pediatric interstitial lung disease, and these are described in detail in

Chapters 54 and 57.

# Clinical Approach

To clarify dialogue among various professionals (obstetricians, perinatologists, pediatric surgeons, pathologists, pediatricians), it is suggested that these principles be followed[6]:

1. What is actually seen should be described without indulgence in embryologic speculation, which may later be proved wrong. Clinical descriptions should not include assumptions of pathology, since the same clinical appearance (e.g., a multicystic mass) may have different pathologic etiologies (see examples previously). Indeed, specific antenatal diagnoses often have to be revised after postnatal excision of the lesion[7]
2. The description should be in common language, discarding Latin.
3. The lung and associated organs should be approached in a systematic manner, because abnormalities are often multiple and associated lesions will be missed unless carefully sought.
4. Pathologic descriptions should describe what is actually seen (epithelial and mesenchymal elements), which may then be related to a diagnostic category (CPAM). However, even distinguished pathologists disagree over the classification of excised specimens, underscoring that clinicans seeing greyscale images are most unlikely to get it right.[2,8]

## Describe What Is Actually Seen

The recommendation to describe what is actually seen should be followed by the clinician both before and after birth. In principle, antenatal ultrasound abnormalities should be described using such terms as increased echogenicity with large, small, or multiple cysts rather than as “CPAM,” which is, and remains, a histological diagnosis. The presence or absence of abnormal feeding vessels should be defined using imaging appropriate to developmental stage (i.e., antenatal or postnatal). Other features, such as mediastinal shift, should also be described. In the postnatal period, a radiographic abnormality should be described as solid or cystic. If cystic, the cysts are either single or multiple, and the uniformity and thickness of the walls should be described. They may be filled with air, or partially or completely with fluid; moreover, their size should be recorded. Postnatally, an air–fluid level suggests that the abnormality is ventilated, albeit with a long time constant. If the lesion has been excised, the pathologist should describe the tissues found (epithelial, mesenchymal) and the contents of any cysts that may be present, thus giving a simple description of what is seen under the microscope. Only then is it relevant to make a pathologic diagnosis, such as one of the various histologic types of CPAM (see subsequent sections). Any classification system that is to be robust cannot be based on embryologic speculation.

## Use Clear Terms

Many terms are ambiguous and are best avoided. For example, hypoplastic lung could be taken as meaning a lung that is small but otherwise normal, or small because the underlying structure is abnormal; the term congenital small lung (CSL, which is what is actually seen) avoids such ambiguity. The use of the term emphysema as in congenital lobar emphysema is another source of confusion, since it implies lung destruction, whereas in at least some variants (e.g., polyalveolar lobe) there may be too many, not too few, alveoli. What is actually seen is a congenital large hyperlucent lobe (CLHL), which is the term that should be used in clinical practice. Throughout this chapter, unwarranted established terms will be given in parentheses after our proposed nomenclature; for the convenience of the reader, the new terms will be spelled out in full, with the abbreviated form being given in parentheses. A summary comparison of old and our current nomenclature is provided in Table 18.1.

---

**Table 18.1**

**Comparison of New and Old Terms Used to Describe the Clinical, but Not Pathological, Appearances of Congenital Lung**

| New Nomenclature | Old Terms Superseded |
|---|---|
| CLHL | Congenital lobar emphysema |
| | Polyalveolar lobe |
| CTM | Cystic adenomatoid malformation (Type 0–4 pathologically) |
| | Sequestration (intrapulmonary and extrapulmonary) |
| | Bronchogenic cyst |
| | Reduplication cyst |
| | Foregut cyst |
| CSL | Pulmonary hypoplasia |
| Absent lung, absent trachea | Agenesis of lung, tracheal aplasia |
| Absent bronchus | Bronchial atresia |

*CLHL*, Congenital large hyperlucent lobe; *CSL*, congenital small lung; *CTM*, congenital thoracic malformation.

## Use a Systematic Approach

The lung can be considered to be formed from six "trees": bronchial, arterial (systemic and pulmonary), venous (systemic and pulmonary), and lymphatic. There are no known congenital abnormalities of bronchial venous drainage, so in practice, only five trees have to be considered. There are three other areas wherein malformations may affect the respiratory system and that should also be assessed. These are (1) the heart and great vessels; (2) the chest wall, including the respiratory neuromuscular apparatus; and (3) the abdomen. Finally, the possibility of multisystem disease (e.g., tuberous sclerosis) should be considered. Each patient suspected of having a congenital lung malformation should be systematically evaluated along these lines, if important coexistent abnormalities are not to be missed. The importance of a systematic approach to treatment, with an appropriate evaluation of all trees and associated systems before embarking on treatment, cannot be overstated.

## Keep Clinical and Pathologic Descriptions Separate

This is an extension of the principle of describing what is seen. Black-and-white images on a scan are unlikely to be pathognomonic of a single histologic entity. It is more logical to describe the clinical appearances and construct a pathologic differential diagnosis. Only after excision of the lesion can the pathologist make an appropriate diagnosis from examination of the excised specimen.

## The Size of the Problem: Epidemiology of Congenital Malformations of the Lung

There is a paucity of high-quality, population-based, epidemiological studies. The requirement for a high-quality study to be performed is for all women in a large population to have access to diagnostic quality, mid-trimester ultrasound scans, which are properly interpreted by experienced radiologists. The European Surveillance of Congenital Anomalies (EUROCAT) is the largest network of population-based registers for the epidemiological surveillance of congenital anomalies including congenital thoracic malformations (CTMs). Current EUROCAT data (2008–2012) reported a prevalence of cystic adenomatoid malformation of 1.05 (95% confidence intervals 0.96–1.15) per 10,000 pregnancies (which included live births, fetal deaths, and terminations of pregnancy), an increasing trend over 4 consecutive years.[9] There was one cluster of cases in Emilia Romagna between mid-April 2010 and the end of February 2011, consisting of 12 cases when 3.65 cases would be expected ($P = .014$). The cause could not be found, and no reason determined further to investigate this cluster. Reported prevalence was 2.55 (2.40–2.71) for esophageal atresia with or without tracheo-esophageal fistula (TEF), a slight increase over time[9] and 2.81 (2.65–2.97) for diaphragmatic hernia.[10] EUROCAT prevalence data, although the best currently available must be treated with caution because the database captures less than 30% of all European data.

## Antenatal Diagnosis and Management of Congenital Lung Disease

The age-related clinical presentations of congenital lung disease are summarized in Table 18.2. Postnatal aspects are described subsequently in this chapter, as are the important abnormalities encountered, which are described in terms of the branching trees comprising the lung.

**Table 18.2**

**Presentation of Congenital Lung Disease by Age**

| Age | Presenting Feature |
|---|---|
| Antenatal | Intrathoracic mass<br>Pleural effusion<br>Fetal hydrops<br>Oligohydramnios or polyhydramnios<br>Other associated abnormalities discovered |
| Newborn period | Respiratory distress<br>Stridor<br>Bubbly secretions in mouth, not able to swallow<br>Failure to pass nasogastric tube<br>Unable to establish an airway<br>Cardiac failure<br>Chance finding<br>Cyanosis in a well baby<br>Poor respiratory effort |
| Later childhood/adulthood | Recurrent infection (including tuberculosis, aspergillus)<br>Hemoptysis, hemothorax<br>Bronchiectasis, bronchopleural fistula<br>Steroid resistant airway obstruction<br>Cardiac failure<br>Malignant transformation<br>Cyanosis<br>Coughing on drinking<br>Chance finding of mass or hyperlucent area on chest x-ray<br>Air embolism (rare) |

## Antenatal Presentation

Antenatal presentation is usually associated with an abnormality detected at the time of a routine fetal anomaly scan as described in detail later. However, abnormalities of amniotic fluid volume may also be associated with underlying pulmonary pathology. This may be secondary, as in bilateral CSL (pulmonary hypoplasia) associated with both early-onset oligohydramnios for whatever reason (bilateral renal dysplasia/agenesis, first- or early second-trimester rupture of the membranes, etc.), or polyhydramnios associated with conditions, such as the Pena-Shokeir phenotype or antenatal onset of severe spinal muscular atrophy, wherein severe neuromuscular disease prevents normal respiratory movements and lung development; another possibility is compression of the fetal esophagus by a mass, preventing normal swallowing of amniotic fluid. In other situations there is a primary pulmonary anomaly (e.g., tracheoesophageal fistula or laryngeal/tracheal agenesis) that causes the polyhydramnios. Other presentations include short limbs in those skeletal dysplasias associated with bilateral CSL secondary to small chests and short ribs (e.g., Jeune's asphyxiating thoracic dystrophy), or talipes and polyhydramnios in congenital myotonic dystrophy.

## What Can We Diagnose and When?

Fetal lung abnormalities are increasingly detected prenatally as a result of advances in ultrasound imaging, which improves the diagnosis, and because fetal anomaly scanning is now routinely offered to many women in the developed world. A fetal lung lesion is suspected either when a mass (cystic or solid) is identified in the thorax or because of mediastinal shift (Tables 18.3 and 18.4). The opportunity to identify an intrathoracic anomaly in the antenatal period permits further investigation and occasionally offers the potential for intrauterine therapy. It also identifies fetuses that may benefit from delivery in a center offering tertiary-level neonatal support and the option of early postnatal surgical intervention. Many of these lesions can be detected around 20 weeks' gestation, but for some, in particular diaphragmatic hernias and pleural effusions, late presentation is well recognized. Such lesions may not be detected until an incidental scan in the third trimester is undertaken, or, indeed, until after birth when the neonate or infant presents clinically. It must also be recognized that a sonographic diagnosis can only describe the macroscopic nature of the lesion, and a definitive diagnosis for many anomalies must await definitive radiologic or histologic diagnosis after birth. Many reported studies are seriously limited, because they base conclusions solely on prenatal ultrasound or postnatal imaging, which is often limited to plain radiology. While advances in technology have improved antenatal diagnosis of lesions that may benefit from early postnatal intervention, many of the abnormalities detected appear to resolve spontaneously or are clinically silent. The pediatrician is frequently faced with a new dilemma: how to manage a healthy infant with a lesion that would not have been brought to medical attention were it not for antenatal imaging. What is the natural history of some of these lesions; do they require intervention, or are they benign variants? This section will present an overview of the antenatal diagnosis and management of the more common types of congenital intrathoracic abnormalities. Postnatal management of the abnormalities is discussed in subsequent sections. A summary approach to counseling mothers whose fetus has a cystic or solid CTM is given in Box 18.1, and discussed in more detail below. The enormous anxiety that is caused by uncertainty, even when the malformation probably has a good prognosis, should be acknowledged.[11,12]

## Table 18.3

### The Differential Diagnosis of Fetal Intrathoracic Lesions

| Solid Lesions | Cystic Lesions |
|---|---|
| Microcystic adenomatoid malformation | Macrocystic adenomatoid malformation |
| Pulmonary sequestration | Congenital diaphragmatic hernia |
| Right-sided diaphragmatic hernia | Bronchogenic cyst |
| Tracheal/laryngeal atresia | Mediastinal encephalocele |
| Rhabdomyoma | Pleural and pericardial effusions |
| Mediastinal teratoma | |

| Total cases seen | 87 | 74 | 12 | 8 | 46 | 6 | 3 | 50 |

[a] Total cases in cohort.

[b] Some cases with conservative management do not have a definitive diagnosis.

[c] Pregnancies were terminated for the following reasons: 45,XO with pulmonary lymphangiectasia, severe hydrops, congenital pulmonary lymphangiectasia, Fraser syndrome (2 cases), Fraser syndrome, and extra lobar sequestration.

[d] Perinatal deaths were secondary to Fraser syndrome, severe hydrops, and pulmonary sequestration with hydrops.

Others included: congenital diaphragmatic hernia (3), pulmonary lymphangiectasia (2), Fraser syndrome (3), eventration of the left diaphragm, teratoma, congenital intradiaphragm cystic lung abnormality, Sturge Weber syndrome, intraabdominal calcification, echogenic mass below abdomen, unclassified abnormal lung, neuroblastoma, and Peter's syndrome with pulmonary hypoplasia.

*CCAML,* Cystic adenomatoid malformation of the lung; *LTFO,* lost to follow-up/WFI, waiting for information (in some cases details of outcome are awaited or the pregnancy is ongoing); *PS,* pulmonary sequestration; *ToP,* termination of pregnancy.

From Bush A, Hogg J, Chitty LS. Cystic lung lesions—prenatal diagnosis and management. *Prenat Diagn*. 2008;28:604-611.

**Box 18.1**

## Suggested Summary Approach to Counseling a Mother Whose Fetus Has an Antenatal Diagnosis of Congenital Thoracic Malformation

The majority of CTMs will increase in size to the end of the second trimester, then regress
Antenatal intervention is very rarely required
Although apparent complete regression of the mass as pregnancy progresses has been reported, many babies are shown postnatally to have persistent abnormalities
Most babies are asymptomatic in the newborn period, and any treatment decisions can be made electively

*CTM*, Congenital thoracic malformation.

In addition to fetal ultrasound, in recent years there has been an increasing use of fetal MRI to define pathology, detected with ultrasound. There are reports of its use for the delineation and evolution of fetal cystic masses,[13–15] but how much MRI adds to the ultrasound diagnosis remains to be demonstrated.[16] It may be more sensitive to small lesions than ultrasound, but it is arguable whether detection of tiny abnormalities really matters. It has been shown to be superior to screening ultrasound for the diagnosis of congenital high airway obstruction syndrome (CHAOS) when it changed the diagnosis in 70%, but in 9 of these 10 cases, the MRI diagnosis was concordant with the referral center ultrasound findings.[17] However, it may be useful to accurately determine the level of airway obstruction in this condition.[18] MRI may also be of use to determine the location of feeding vessels in fetuses with pulmonary sequestration,[19] but further comparison with ultrasound-based methods is required before we can say whether it adds significantly to Doppler-based methods. The role of MRI to determine lung volumes in fetuses with congenital diaphragmatic hernia (CDH) or lung masses has been evaluated[20] and may ultimately prove superior to other ultrasound-based methods (see later). Finally, virtual bronchoscopy can be undertaken with fetal MRI.[21,22]

## Specific Diagnoses: Congenital Diaphragmatic Hernia

The prenatal incidence of CDH is around 1 in 2000. There is a wide variety of abnormalities associated with CDH including aneuploidy, in particular Trisomy 18 and 13, genetic syndromes and structural abnormalities. Many of these will result in a stillbirth or termination of pregnancy, so isolated CDH is much more common in neonates. Anomalies associated with this condition include neural tube defects, such as myelomeningocele, cardiac defects, and midline anomalies, such as cleft lip and palate. Genetic syndromes, such as Fryns syndrome, can account for up to 10% of cases in some series. The herniation of abdominal contents into the chest inhibits normal lung development resulting in pulmonary hypoplasia, which, in isolated lesions, is the main cause of death.

The diagnosis of a left-sided CDH is usually first suspected when a mediastinal shift is observed and abdominal viscera are seen within the fetal thorax (Fig. 18.1). The most useful clue is usually the identification of a cystic structure (the stomach) in the chest together with absence of an intraabdominal stomach. The observation of peristalsis in the chest can also be a useful clue as loops of bowel may be difficult to distinguish from other cystic lesions. Occasionally it is possible to observe paradoxical movement of the viscera in the chest with fetal breathing movements. Once alert to the possible diagnosis, careful radiological examination of the fetus in the coronal and parasagittal planes will show the diagrammatic defect. Right-sided CDH are more difficult to recognize as it is usually just the liver that is herniated, and this is of similar echogenicity to lung tissue. Often the only clue is mediastinal shift, and this may not be apparent at the time of a routine anomaly scan unless the degree of shift is great. Sometimes the diagnosis is made when a scan is performed in the third trimester because of polyhydramnios resulting from the presence of herniated abdominal contents in the chest, which prevents normal swallowing movements and results in late onset of increased amniotic fluid.

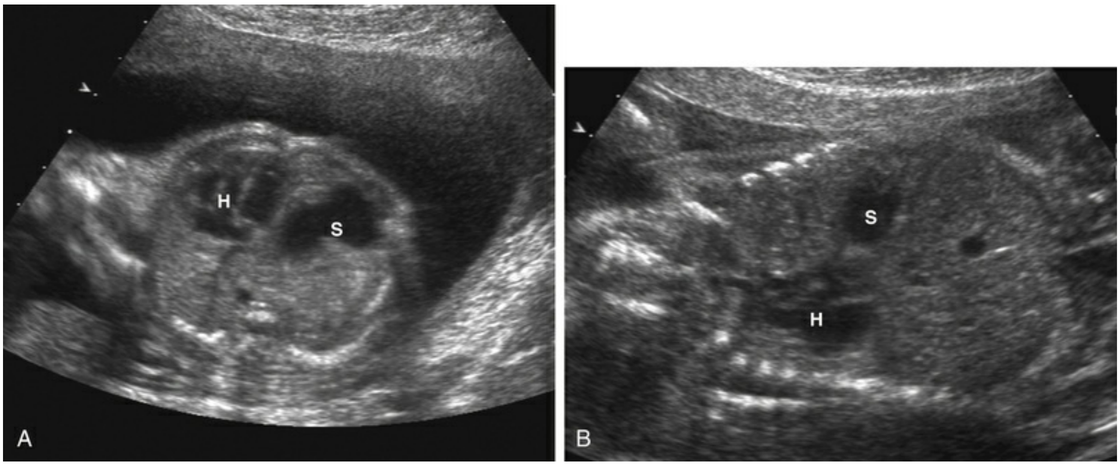

**FIG. 18.1** Transverse view through the thorax at 20 weeks' gestation in a fetus with a diaphragmatic hernia. (A) The stomach (S) is seen displacing the

heart (H) to the right. In the longitudinal plane (B), no diaphragm can be seen and the stomach is in the chest.

The overall prognosis for fetuses with CDH is poor with the major causes of death being pulmonary hypoplasia and/or the associated abnormalities. The time of diagnosis is related to outcome with those diagnosed early faring the worst. Lung size, expressed as lung-to-head ratio (LHR) or the observed-to-expected LHR measured by ultrasound[23] and the observed-to-expected total lung volume as measured by MRI and liver herniation are reasonable predictors of neonatal outcome.[24] However, they are not good predictors of other poor outcomes, such as pulmonary hypertension.[25] Other poor prognostic indicators include evidence of liver within the chest and cardiac disproportion before 24 weeks. Isolated left-sided hernias, an intraabdominal stomach, and diagnosis after 24 weeks are favorable prognostic factors. Survival in these cases is now more than 60% (Table 18.5).[26]

## Table 18.5

[a] Only isolated left-sided CDH cases were included in study.

[b] Only right CDH were included in study.

[c] Overall survival has increased during the period of the study from 19% (1968–1971) to 54% (1996–1999).

Where there are no figures for the survival, data were not given in the publication.

*CDH*, Congential diaphragmatic hernia.

Following the prenatal diagnosis of CDH, management should include a detailed search for other anomalies and fetal karyotyping. Expert fetal echocardiography is indicated as examination of the heart is complicated by distortion of intrathoracic contents. Consultation with a pediatric surgeon should be offered and, given the variable prognosis both in terms of perinatal mortality and morbidity, termination of pregnancy is an option that should be discussed. Intrauterine surgery has been performed for CDH. In principle, the airway is occluded and the continued secretion of lung liquid beyond the obstruction leads to expansion of the lung. Early studies involved an open procedure including hysterotomy, which is demanding and carries significant maternal risks, including complications in future pregnancies, as well as the possibility of precipitating preterm labor. Furthermore, although there was some apparent improvement in outcome following in-utero surgery, there has been no well-designed, randomized, controlled trial, so it is not possible to objectively assess the benefits and costs.[27] More recently, fetal endoscopic tracheal occlusion (FETO) using a variety of methods has been used and is currently the only approach used clinically.[28] The currently favored method for FETO is using an inflatable balloon that is placed in the trachea endoscopically. Compared to historical controls in large series, FETO does seem to improve neonatal survival, with preterm labor being the most common complication of pregnancy,[29] and many infants develop tracheomalacia or tracheomegaly (Fig. 18.2).[30] There is now an international randomized controlled trial of FETO in progress. These results are needed, together with long-term follow-up of children who underwent *in utero* therapy, before the true value of this procedure can be accurately evaluated.

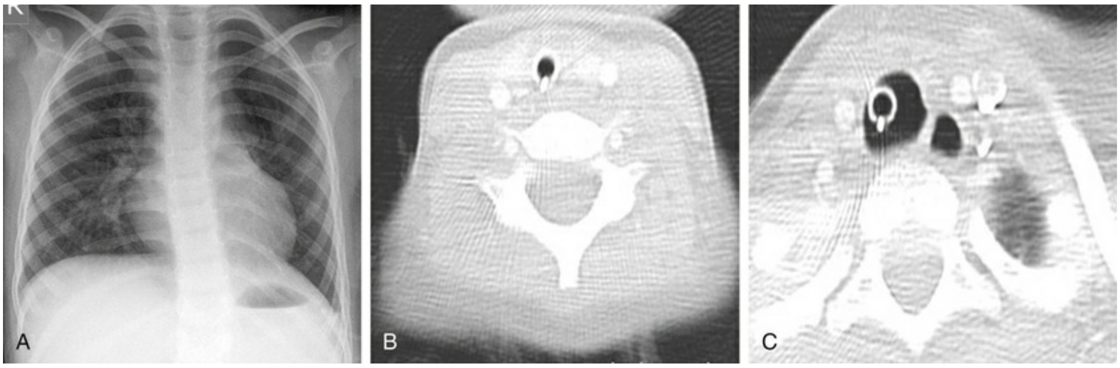

**FIG. 18.2** (A) Plain chest radiograph of an infant treated in utero with FETO. Note the huge trachea. (B) High-resolution computed tomography showing the infant has been intubated with an endotracheal tube, which fits snugly in the cervical trachea. (C) The intrathoracic trachea is hugely dilated.

Delivery of any ongoing pregnancy should be planned in a center with neonatal intensive care and pediatric surgical facilities. In the event of fetal or perinatal death, a postmortem examination is recommended. This should include a genetic opinion in order to facilitate an accurate diagnosis of any possible underlying syndrome, which may confer an increased risk of recurrence in future pregnancies.

## CTM Subsequently Diagnosed Postnatally as CPAM

### Antenatal Diagnosis and Prognosis

CPAM is traditionally classified according to histological and clinical findings; however, sonographic classification is best achieved by considering them as either macrocystic (Fig. 18.3) or microcystic (Fig. 18.4).[8] The main differential diagnosis to consider with a macrocystic CPAM is diaphragmatic hernia. Differentiating features are described above. However, in a series of 87 fetuses seen in the Fetal Medicine Unit at University College London Hospitals (UCLH) with a prenatal diagnosis of CPAM, two in fact had a diaphragmatic hernia and one an eventration of the diaphragm (see Table 18.4). In those with a diaphragmatic hernia, the correct diagnosis was made prenatally after serial scanning. In the patient with an eventration, the correct diagnosis was made only on postnatal imaging.[31] Most CPAMs occur in isolation, although other abnormalities, including bronchopulmonary sequestration and CDH, have been reported to occur in association with CPAM as they have a broad range of extrapulmonary malformations, including renal and cardiac anomalies.[32,33] Indeed, differentiation of these lesions histologically can be challenging as many have a mixed etiology.[2–5] Aneuploidy is not a recognized association.

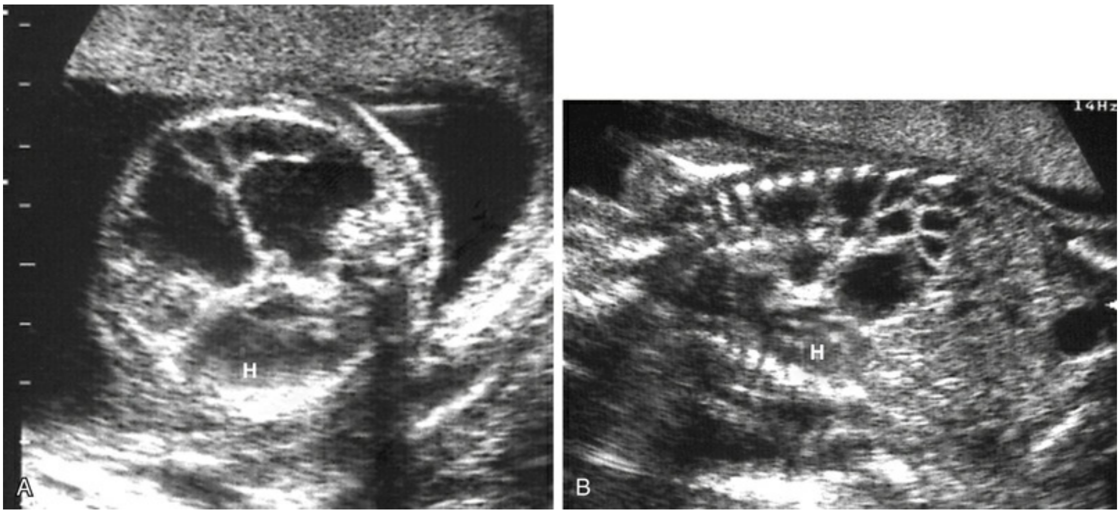

**FIG. 18.3** Axial (A) and longitudinal (B) view through the fetus thorax in a fetus referred at 21 weeks' gestation with skin edema and increased liquor. The heart (H) can be seen displaced to the left, and the whole chest appears to be full of abnormal lung tissue. In the longitudinal view the diaphragm is displaced downwards by the abnormally expanded lung tissue. The large cysts were aspirated and pleuro-amniotic shunts inserted, following which the skin edema resolved. The pregnancy continued to term; respiratory

support was required at birth with surgery in the neonatal period. The child is now alive and well at school age.

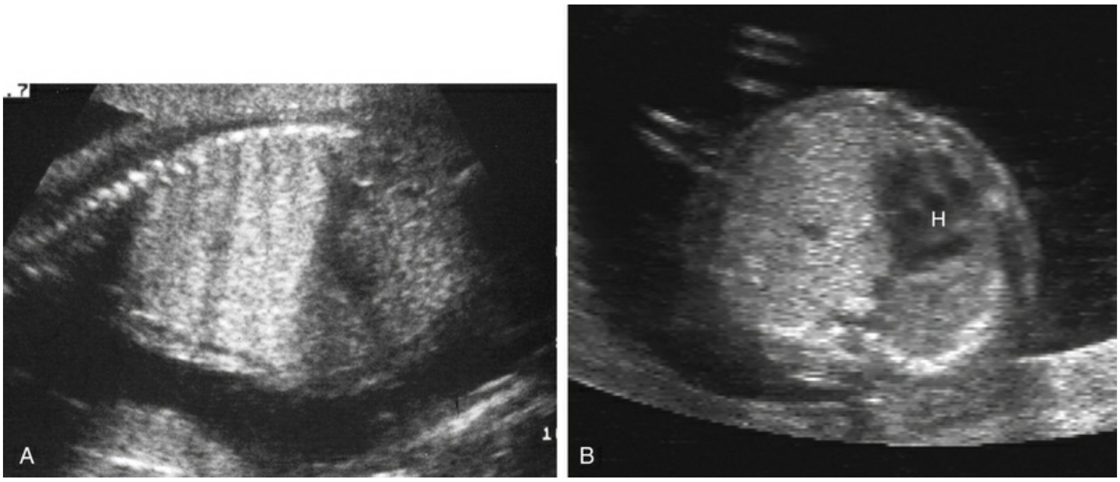

**FIG. 18.4** (A) Parasagittal view through the chest at 21 weeks' gestation showing the echogenic wedge-shaped left lower lung behind the chest in a fetus with a microcystic lesion. In the axial view of the fetal chest (B), the abnormal lung can be seen causing marked mediastinal shift with the heart (H) lying in the right chest. The mediastinal shift resolved as pregnancy progressed, and the baby was well at birth. Postnatal imaging confirmed the presence of the lesion, and a conservative management policy was followed.

In general, the prognosis for a fetus with a CPAM is good with only a small number going on to develop hydrops, which is a poor prognostic sign, particularly if it is evident at the initial presentation in the second trimester.[31] Traditionally, both polyhydramnios and mediastinal shift were considered poor prognostic indicators, but data that are more recent suggest that these may be less reliable. Accurate prediction of outcome for prenatally diagnosed lesions can be difficult following a single scan because they can change in size significantly during pregnancy with the majority reducing in size and many appearing to disappear spontaneously. Some may increase in size until around 26 weeks' gestation before reducing in size, while others appear to resolve on sonography.[34] Spontaneous resolution of features, such as hydrops or mediastinal shift, which are usually associated with poor prognosis,[35] has been observed. Various attempts have been made to predict outcome using models that include cyst volumes,[36] but the varied course of these lesions means that serial scans are required to detect those lesions that progress in size or display adverse prognostic features that may warrant consideration of intervention. The Kings College London group has reported on 67 fetuses with an antenatally diagnosed congenital lung malformation.[37] A total of 64 were born alive, and 42 underwent postnatal surgery (see later). Surgery was performed in 45% of lesions showing late gestation "resolution." Although there was some correlation between the antenatal appearances and the need for surgery, this was not usefully predictive for an individual, and the need for operation was judged on the postnatal features of clinical need. In a case series of 119 neonates with an antenatal diagnosis, and who were followed up to the age of 5–16 years, and were cared for at Great Ormond Street Hospital (GOSH),[38] only 8 (6.7%) were symptomatic and required emergency surgery during the neonatal period. This is in keeping with another large case series from the University of Southampton of 72 neonates with a prenatal diagnosis of congenital lung malformation, where only one required emergency surgery.[39] The use of elective surgery remains controversial[40] as indicated by the lower rate of surgery overall (43%) in the GOSH cohort where surgery was usually only performed on clinical grounds compared with the Kings series, and these data demonstrate the varying approach to management. Table 18.4 shows the type of cystic lung lesion, other sonographic findings, diagnosis, and outcome for the UCLH cohort.[31] In all cases, early consultation with neonatal and pediatric surgical staff is helpful for parents.

## Antenatal Treatment Options

There is very little agreement on definitions, even for something as basic as fetal hydrops, and only a limited evidence base as to the antenatal options for treatment. There have been no randomized, controlled trials,[41] so small case series are the only basis for decision making. Most would agree that an expectant approach is best, reserving treatment for hydropic fetuses, or perhaps in the rare case with a rapidly expanding lesion in the last trimester. Even in large units, the performance of invasive interventions is unusual.[37] The least aggressive intervention is the administration of betamethasone to the mother for which there is limited reported experience.[42–46] In a case series of nine patients who had not responded to a single dose, repeat doses led to stabilization ($n = 4$), improvement ($n = 3$) or had no effect and the lesion progressed, necessitating antenatal surgery, both of whom died, as did one other baby.[44] Obstetric complications in the mother were common, mandating careful follow-up. Long-standing requirements for fetal surgery are shown in Box 18.2,[47] and these are surely applicable to any antenatal intervention for a CTM. However, intrauterine surgery is increasingly performed for a widening spectrum of diagnoses,[48] including CTMs.[49,50] Where there are single or multiple large cysts (see Fig. 18.3) with associated hydrops or polyhydramnios, in-utero decompression by thoracentesis or the insertion of a shunt has led to improvement.[51,52] Intrauterine surgery to remove these lesions has been reported, but has been very rarely undertaken due to the associated fetal mortality and maternal morbidity.[51] In one small series, the outcomes of shunting were good, and decompressing a single cyst was sufficient to cause the mass to collapse; it was suggested that shunting might be indicated early, before hydrops develops, in high-risk lesions.[53] Other surgical options include fetal sclerotherapy[49,54,55] and radiofrequency ablation. However, fetal death has resulted from this last technique.[36] Percutaneous laser ablation, guiding the beam into the fetal thorax via a fine needle placed under ultrasound control may be aimed at vascular or "interstitial" ablation.[56] The results were best for babies with a postnatal sequestration (87.5% survival) rather than CPAM (28.6%), and the immediate results were better with vascular ablation. It is concerning that marked postnatal chest deformity has been associated with fetal shunt insertion. Finally, there are case reports of interventional fetal bronchoscopy to treat congenital lesions with a poor prognosis[57,58]; as always, it is difficult to assess such reports, and this intervention must be considered highly experimental until more data become available.

### Box 18.2

### Requirements for Fetal Surgery for Congenital Thoracic Malformation, Which Are Equally Applicable to Other Antenatal Interventions

A CTM causing hydrops or preventing acceptable fetal lung development

Singleton fetus with no other important abnormality

Serial assessment to ensure the CTM really requires fetal surgery, and is salvageable

Family counseled and agree to treatment and long-term follow up

Multidisciplinary team agree on a treatment plan

Access to high level obstetric and neonatal care, and bioethical and psychosocial consultation

*CTM*, Congenital thoracic malformation.

Where a lesion has persisted, or increased in size, and mediastinal shift persists in the third trimester, delivery in a center with neonatal intensive care and surgical facilities is indicated. In all cases there should be careful postnatal follow-up, with computed tomography (CT) being offered to all. There are many examples of lesions that apparently involuted completely in utero being present when examined by CT after birth.

## Congenital Thoracic Malformation Subsequently Diagnosed Pathologically as Bronchopulmonary Sequestration

In the fetus a sequestrated lobe of lung is most often identified as a mass of uncertain origin in the chest or subdiaphragmatic area. Prenatally it is not possible to make a definitive diagnosis unless an independent blood supply is demonstrated using Doppler ultrasound, although it should be noted that a CPAM might also have an aortic blood supply. The sequestrated lobe usually appears as an echogenic mass in the chest (Fig. 18.5) or abdomen (Fig. 18.6). It can be associated with hydrops, mediastinal shift, and polyhydramnios (see Fig. 18.5). The outcome for fetuses with bronchopulmonary sequestration is generally good when presentation is uncomplicated by pleural effusions or hydrops. As such, the prenatal management of fetuses with lesions suspected to be a sequestration is similar for those with a suspected CPAM; therefore, serial scanning should be undertaken and the fetus should be delivered in a tertiary unit if there is significant mediastinal shift in the third trimester. Spontaneous improvement in utero is frequently reported. In a review of the literature describing neonatal outcomes after in-utero interventions, laser coagulation of the feeding vessel to a sequestrated lobe in hydropic fetuses has been reported to result in the resolution of the hydrops and a good neonatal outcome in several cases.[59]

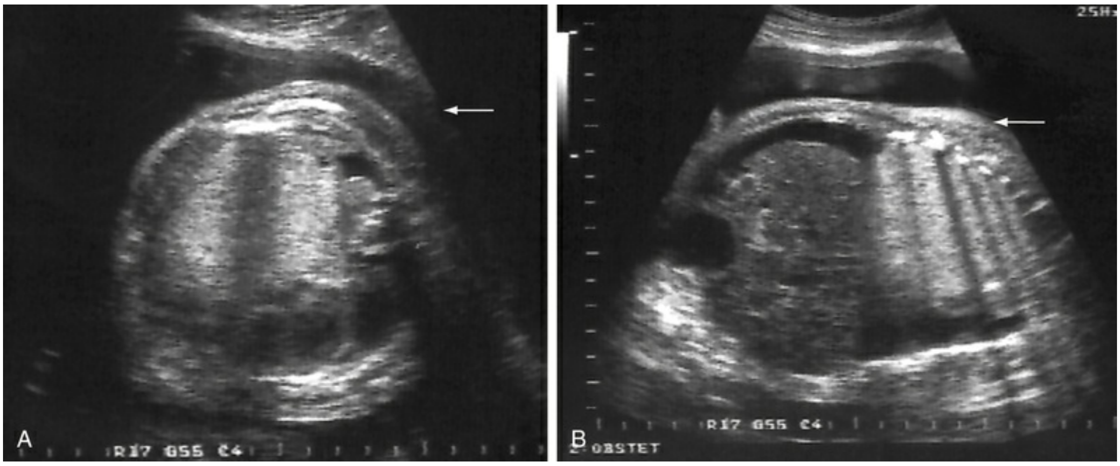

**FIG. 18.5** Axial (A) and longitudinal (B) view through the thorax of a fetus that presented at 34 weeks' gestation with hydrops and polyhydramnios. The large echogenic mass can be seen occupying most of the chest. There is a significant rim of ascitic fluid seen in the abdomen as well as pleural effusions in the chest. Preterm labor ensued after amniodrainage. Resuscitation failed and a postmortem demonstrated a sequestrated lobe with associated pulmonary hypoplasia.

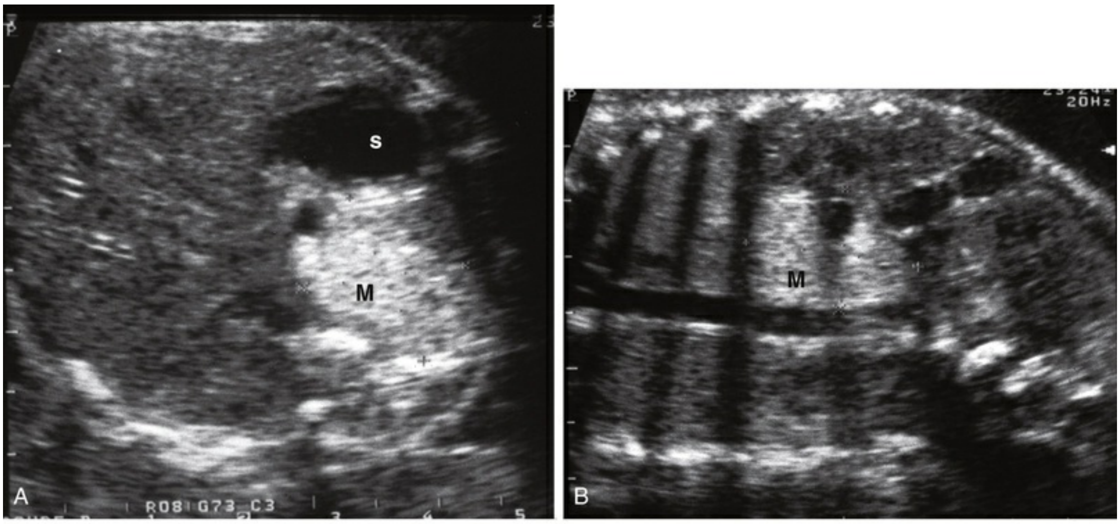

**FIG. 18.6** Axial (A) and longitudinal (B) view through the abdomen of a fetus at 22 weeks' gestation. Note the echogenic mass (M) related to the diaphragm lying behind the stomach (S). An ultrasound-guided needle biopsy after birth confirmed this to be a pulmonary sequestration. This subsequently resolved spontaneously in early childhood.

## Presentation of Congenital Thoracic Malformations in the Immediate Postnatal Period

Postnatal presentations of many abnormalities of course overlap; in summary, presentation is with immediate neonatal respiratory distress; the delayed development of symptoms or a complication of a known or previously undiagnosed abnormality; or the child may have an asymptomatic lesion for which active management may or may not be indicated.

The differential diagnosis of acute unexpected respiratory distress in a term newborn extends well beyond congenital lung disease to include conditions such as congenital infections, interstitial lung disease, pneumothorax, cardiac disease, and primary ciliary dyskinesia. If a congenital lung abnormality has been identified antenatally, the diagnosis of the cause of the respiratory distress is likely obvious. Not all lesions are detected prenatally, although with increasing use and improvements in technology and sonographic skills, postnatal presentation is becoming less common. Late detection may particularly be an issue in diaphragmatic hernias, some of which do not present with sonographic findings until after the time of the routine anomaly scan, or, indeed, well after birth. Respiratory distress in the absence of major airway disease may be due to disorders of the lung parenchyma. These include a large cystic or solid CTM, the presence of unilateral or bilateral small lungs, and congenital pleural effusion or lymphatic disorder. The differential diagnosis of a cystic abnormality detected postnatally, but not antenatally, includes cysts secondary to infection[60] or pulmonary interstitial emphysema,[61] which may present in localized form even in a term baby who has not been ventilated.

The management of CTMs after the immediate postnatal period, both asymptomatic and those that have become symptomatic after a latent period of as long as many years, is discussed below. The King's College Hospital group (see earlier)[37] actually performed surgery in 45% of lesions showing late-gestation “resolution.” Although there was some correlation between the antenatal appearances and the need for surgery, this was not usefully predictive for an individual, and the need for an operation was judged on postnatal features rather than clinical need. In general, the approach to the postnatal management of neonates with prenatally diagnosed cystic lung lesions is very variable. There are those who feel that all lesions should be surgically removed, and others who favor a more conservative approach (Table 18.6). At UCLH, we have seen 110 fetuses with cystic lung lesions in the last 15 years, of whom 100 are alive, 20 having had surgery. This is a much lower proportion than in the King's series and demonstrates the varying approach to management. In all cases, early consultation with neonatal and pediatric surgical staff is helpful for parents. The issues of postnatal management are discussed in more detail below. Where a lesion has persisted or increased in size and mediastinal shift persists in the third trimester, delivery in a center with neonatal intensive care and surgical facilities should be considered. In all cases, careful postnatal follow-up should be undertaken, with CT being offered to all, even if the lesion has apparently disappeared completely antenatally; chest x-ray (CXR) is only 61% sensitive to the presence of lesions on high-resolution computed tomography (HRCT).[62] Lesions that have apparently involuted completely in utero are well documented to still be present when examined by CT after birth.

### Table 18.6

### Reported Outcomes and Postnatal Management in Recent Series of Cystic Lung Lesions

[a] Only large lesions.

[b] Only severe hydrops.

[c] Only reports antenatally diagnosed cases who were asymptomatic.

Numbers in parentheses refer to cases with no signs on postnatal imaging either. Other diagnoses include CDH, tracheal atresia, etc.

*CDH,* Congential diaphragmatic hernia; *IUD/PND,* intrauterine or perinatal death; *LTFU,* lost to follow-up; *ToP,* termination of pregnancy.

Modified from Bush, Hogg J, Chitty LS. Cystic lung lesions—prenatal diagnosis and management. *Prenat Diagn*. 2008;28:604-611, with permission from Wiley Blackwell.

Vascular abnormalities may present at this time. One such group are aortopulmonary collaterals supplying either a CSL or a CTM. These act hemodynamically as systemic arteriovenous malformations and cause high-output heart failure. Abnormalities of venous drainage, such as "scimitar" syndrome (hemianomalous pulmonary venous drainage to the inferior caval vein), may also present as heart failure or enter the differential diagnosis of pulmonary hypertension in the newborn period. Other vascular problems that may present at this time include alveolar-capillary dysplasia (discussed in Chapter 54) and pulmonary arteriovenous malformation (PAVM), which may present as cyanosis in a well infant (not with heart failure, unless there is an associated systemic, usually cerebral, arteriovenous malformation). The presentations of congenital lung disease after the postnatal period, and the issues around prophylactic surgery, are discussed in more detail below.

## Specific Diagnoses: Upper Respiratory Tract Atresias

Laryngeal or tracheal atresia are rare malformations that may be isolated or found in association with other abnormalities or genetic syndromes, the most common of which is Fraser syndrome.[63] The diagnosis of laryngeal or tracheal obstruction should be suspected when enlarged, uniformly hyperechogenic lungs are seen on ultrasound (Fig. 18.7). Other sonographic features include cardiac and mediastinal compression, flattening or convexity of the diaphragms, hydrops, and polyhydramnios. A dilated, fluid-filled upper trachea can also be seen in tracheal atresia (Fig. 18.8). The differential diagnosis of laryngeal or tracheal atresia includes subglottic stenosis (SGS) and bilateral microcystic CCAM. When associated with Fraser syndrome, there may be renal anomalies, syndactyly of fingers and toes, and cryptophthalmos. The prognosis is invariably poor, and the option of termination of pregnancy should be discussed. Parents should also have the opportunity to discuss the prognosis with a pediatric surgeon, and, if the pregnancy is continued, delivery should be planned in a unit with neonatal intensive care and pediatric surgical facilities. Prenatal analysis of chorionic villi or amniocytes using exome sequencing may help reveal any underlying genetic etiology, which will aid prenatal counseling.[64] Rarely, antenatal tracheostomy has been reported, although this may precipitate fetal distress and preterm delivery.[65] Ex utero intrapartum treatment (EXIT procedure) has been reported (below).

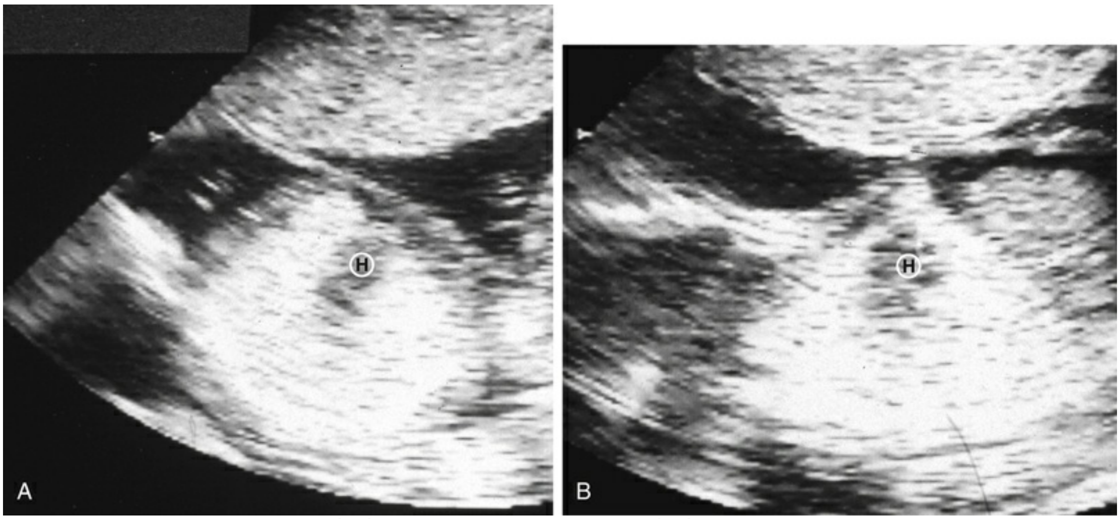

**FIG. 18.7** Axial (A) and longitudinal (B) view the thorax of a fetus at 19 weeks' gestation with tracheal agenesis. The lungs are completely bright and can be seen compressing the heart (H) in (A). In the longitudinal plane, the diaphragms are displaced downwards by the expanded lung issue.

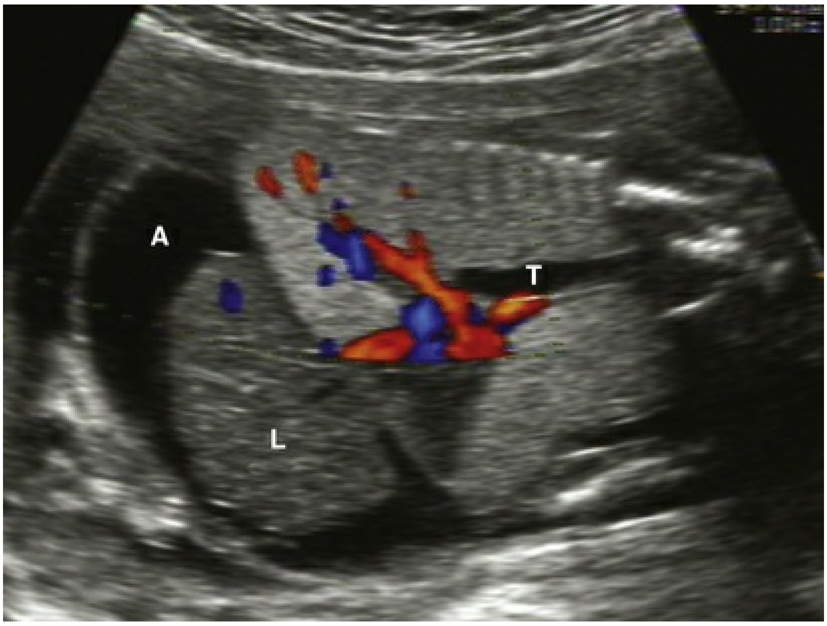

**FIG. 18.8** Longitudinal view of a fetus with tracheal agenesis. The heart can be seen highlighted by the color Doppler with the abnormally dilated trachea (T) seen as a fluid-filled structure in the mediastinum. The lungs bulge downwards into the ascites (A) in the abdominal cavity in which the liver (L) can be seen.

# Specific Postnatal Problems: Congenital Abnormalities of the Upper Airway

This section will detail the variety of different congenital abnormalities that involve the upper airway and will deal with clinical problems involving the larynx and trachea. Though this section will not cover the complete spectrum of congenital disorders that can cause respiratory disorders in neonates, the pediatric otolaryngologist will be experienced in dealing with airway problems due to congenital abnormalities involving the whole airway from the anterior nares to the bronchi. The abnormalities may be intrinsic or extrinsic to the airway and be single or multiple. The spectrum of disorders is detailed in Tables 18.7 and 18.8.

---

**Table 18.7**

### Congenital Conditions Above the Larynx and Trachea Causing Neonatal Airway Obstruction

| | |
|---|---|
| **INTRINSIC** | |
| Nose | Atresia (absence); e.g., arhinia |
| | Choanal atresia (complete obstruction) |
| | Piriform aperture stenosis (narrowing)<br>Severe craniofacial abnormalities; e.g., hemifacial microsomia (Goldenhar syndrome) and the mid-facial syndromes (e.g., Apert or Crouzon syndrome) |
| Oral Cavity and | Macroglossia; e.g., Pierre-Robin sequence |
| Oropharynx | Retrognathia; e.g., Treacher-Collins syndrome |
| **EXTRINSIC** | |
| Viscero-cranial and | Lymphatic malformations; e.g., cystic hygroma |
| Neck masses | Vascular malformations; e.g., arterio-venous malformation |
| | Vascular tumors; e.g., capillary hemangiomas |
| | Encephaloceles |

## Table 18.8

### Congenital Abnormalities of the Larynx and Trachea

| | |
|---|---|
| Larynx | Laryngeal atresia and webs |
| | Laryngeal cleft |
| | Laryngomalacia |
| | Vocal cord paralysis |
| | Saccular cysts and laryngoceles |
| | Subglottic hemangiomas |
| | Congenital subglottic stenosis |
| Trachea | Tracheomalacia |
| | Congenital tracheal stenosis |
| | (complete tracheal rings) |

These abnormalities may present with immediate respiratory distress at delivery but may equally be more subtle in their clinical symptoms and signs. Airway abnormalities should be considered in the presence of an abnormal cry, weak or husky voice, or recurrent crouplike episodes. Difficulties with feeding may also be a feature of airway abnormalities, such as laryngomalacia or laryngeal cleft. In these situations, there may be recurrent episodes of aspiration with feeding (laryngeal cleft) or respiratory distress and gastroesophageal reflux (laryngomalacia)

This text aims to offers a practical guide to the management of airway obstruction. This initial section describes a comprehensive assessment of a child presenting with stridor in the office-based scenario moving onto management of this child, including descriptions of common elective procedural-based assessments. The subsequent sections augment the discussion of airway management with consideration of the acutely unwell child presenting in the emergency room and the increasingly common scenario we are faced with in the hospital setting concerning children with intubation/extubation difficulties. As always, the appropriate assessment of pediatric airway problems commences with clinical history taking and examination.

## Stridor

Quite often the most important feature in the history is the time of onset and character of stridor. Stridor present since birth most indicates a congenital pathology, such as laryngeal webs or bilateral vocal cord paralysis, whereas a more gradual onset of symptoms over days/weeks to months points to diagnoses such as laryngomalacia, subglottic hemangiomas, or cysts. An acute onset of symptoms, accompanied by corroborating factors in the history, can lead towards diagnosing foreign body aspiration and inflammatory or infectious conditions as the etiological factor (see Chapter 23). The characteristics of the stridor itself can also be a diagnostic aid: inspiratory suggests glottic pathology (and that in the immediate supraglottis); biphasic subglottic or extra thoracic trachea pathology; and expiratory intrathoracic, trachea, and bronchial pathology. Another diagnostic indicator of stridor is its character. Stridor of a constant nature indicates a fixed lesion pathology as opposed to the intermittent symptoms of conditions such as laryngomalacia.

## Voice/Cry

In addition to stridor there are other laryngeal symptoms that should be taken into consideration such as the voice/cry and cough. These symptoms particularly implicate glottis level pathology, either structural (webs, papilloma) or functional (vocal cord paralysis).

## Cough

Cough itself can be associated with other factors in the history, such as its relation to upper respiratory tract infections (URTIs) and croup. If there is a history of recurrent or prolonged croup, consideration should be given to the need to diagnose an underlying airway stenosis or inhaled and retained foreign body, or subglottic hemangioma. Cough can also be related to aspiration events related to feeds where, with the aid of swallowing, assessment of the presence of vocal cord palsy, laryngeal cleft, or TEF may need to be investigated.

## Cyanosis

Episodes of cyanosis certainly indicate severe respiratory difficulty and can be due to several causes, but they are often associated with tracheal disease, including external compression due to the presence of a vascular ring.

## Neonatal Intubation

Perhaps one of the most important factors in the history should be that pertaining to the birth history and, more specifically, neonatal intubation. Respiratory difficulty at birth and the need and duration of intubation and ventilation should lower the threshold for proceeding to diagnostic microlaryngobronchoscopy (MLB) in those children with an otherwise less concerning symptomatic history. Subglottic cysts and acquired stenosis are often an endoscopic finding in these cases. The premature infant is therefore often in this high-risk group for airway pathology. Additionally, this patient subgroup is also more likely to have undergone cardiac surgery, which can be associated with upper airway pathology, such as recurrent laryngeal nerve palsy.

## Other Comorbidities

These should also be sought in the history as these can be associated with particular pathologies. Many of the craniofacial syndromes are associated with airway difficulties that are often multilevel problems. Down syndrome children are known to have difficulties due to macroglossia and congenital SGS. There are also several conditions that can be associated with hypotonia, such as cerebral palsy, leading to airway difficulties.

## Examination of a Child Presenting in the Clinic Setting

This starts with appropriate exposure and inspection to allow an overall assessment to be made about the severity of respiratory distress as well as diagnostic clues to the underlying pathology. The presence and nature of stridor can indicate the level of likely airway pathology as previously discussed. Chest wall movement, the use of accessory muscles, tracheal tug, sternal recession and subcostal or intercostal recession, nasal flaring and head bobbing, the voice/cry, the presence of cutaneous hemangiomas, and any dysmorphic features should be given careful consideration. In particular, craniofacial abnormalities are likely to impact on the airway, and the most common ones include macroglossia and retrognathia. The oral cavity should always be inspected as part of the airway assessment and, in addition to tongue and mandibular features, tonsillar pathology (size) should also be taken into consideration. Obstructive airway problems, such as these at the oropharyngeal level, lead to stertor and, therefore, can be distinguished from those causes of stridor at a more distal level. The nasal airway also should be assessed for patency to exclude choanal atresia.

Fiberoptic nasoendoscopy (FNE) should be performed where possible to complete an airway assessment in the office/clinic setting. With parental cooperation, this can be achieved in infants and in the older child, but it may be more challenging in the 2- to 5-year-old age group where restraint is often not practical. Topical nasal preparations of local anesthetic combined with decongestant can be used to aid the examination with the fiberoptic scope; this is often used in the older child, but is often omitted in the examination of the infant. FNE is particularly useful to assess nasal anatomy and pathology down to the glottic level with conditions such as choanal atresia and laryngomalacia readily diagnosed with this technique. It can also identify other supraglottic pathology, such as vallecular cysts, and such information can be beneficial in planning airway assessment under general anesthetic (Fig. 18.9). However, it is unsuitable to evaluate pathology at a more distal level to the glottis.

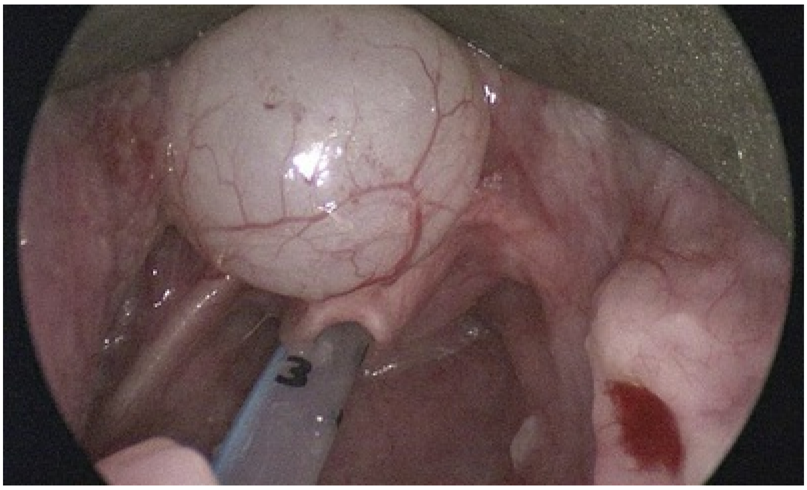

**FIG. 18.9** A large vallecular cyst seen on fiberoptic nasoendoscopy. It was subsequently excised at microlaryngobronchoscopy.

Definitive assessment of the airway is by means of a diagnostic MLB performed under general anesthetic. This technique allows for a full structural and dynamic assessment of the upper airway from nares to bronchi. Increasingly, MLB techniques have developed to allow treatment as well as diagnosis in conditions previously considered only to be amenable to open airway surgery. Successful MLB relies on good collaboration between the surgical and anesthetic teams. The technique requires an anaesthetized but spontaneously ventilating patient with a nasal prong and gas/air mix or with titrated total intravenous anesthesia (TIVA). The larynx is sprayed with a local anesthetic solution to reduce the depth of anesthesia required to allow instrumentation of the larynx; however, this may exaggerate the appearances of laryngomalacia.[66] The patient should be positioned with a head ring and shoulder roll to achieve the optimal position for airway endoscopy. Diagnostic MLB can be performed successfully with an anesthetic straight or curved blade laryngoscope and a zero-degree Hopkins rod of the appropriate size, usually 4 mm. This simple technique with minimal instrumentation allows the main subsites to be visualized without major irritability to the airway. If required, suspension MLB can then be performed using one of the many laryngoscopes that are available. This technique is preferred for treatment purposes when a two-handed approach is required. The ventilating bronchoscope should always be available. Once the airway subsites have been assessed, the cricoartytenoid joints are palpated for fixation and interarytenoid area for a laryngeal cleft, any stenosis present is sized with an endotracheal (ET) tube and, finally, a dynamic assessment should be made checking for vocal cord movement in addition to any supraglottic prolapse due to laryngomalacia.

## The Emergent/Marginal Airway and Difficult Intubations

### Definition

The *Emergent Airway* is that transition point at which a patient's oxygen saturation becomes difficult or impossible to maintain above 90% during an intubation or procedure.

Assessment of a neonate presenting in an emergency with airway difficulty is often an unnerving situation for all concerned. It is important to have a clear and methodical plan to implement in these circumstances to aid prompt diagnosis and appropriate intervention. The history is again important and should aim to cover those points discussed in the previous section. Immediate examination in the delivery room may provide an obvious diagnosis by the pediatric staff, such as a major craniofacial abnormality, but severe airway problems, such as congenital tracheal stenosis, may have no external physical signs.

Accordingly, it is not unusual for children to be stabilized by the attending pediatric team before a definitive diagnosis is made. This might include intubation of the child; the use of oral airways in the case of nasal obstruction (e.g., choanal atresia); nursing the child prone in cases of oral/oropharyngeal obstruction (e.g., in Pierre-Robin sequence); and the use of a nasopharyngeal airway (NPA) if the obstruction is not easily relieved. If intubation is extremely difficult, it may be appropriate to consider immediate tracheostomy to avoid the risk of the ET tube becoming dislodged and failure to reintubate. This might be considered with a large cystic hygroma (Fig. 18.10). If the anatomy of the neck is very abnormal, it may be useful to pass a rigid bronchoscope to allow ventilation and act as a marker for the trachea within the distorted anatomy of the neck.

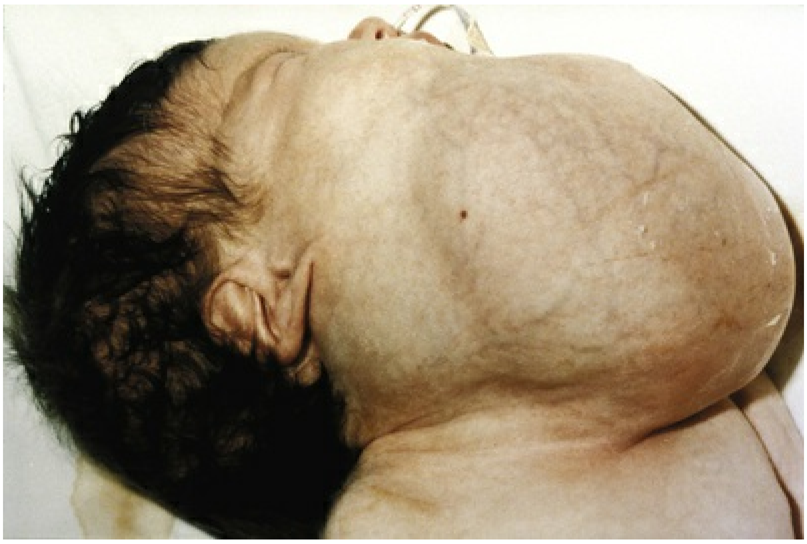

**FIG. 18.10** Severe neonatal upper airway obstruction due to cystic hygroma. (Picture reproduced courtesy of Mr. C.M. Bailey.)

As outlined above, a child who has chronic or episodic stridor may be examined with a flexible endoscope to assess the upper airway and diagnose supraglottic pathology. The requirements for this procedure to be performed safely are given in Box 18.3.

**Box 18.3**

## Requirements for Safe Upper Airway Endoscopy

Small diameter endoscope (ideally 1.8 mm)
Access to pediatric resuscitation equipment and personnel, especially skilled pediatric anesthesiology

Stable neonate (minimal oxygen or air pressure support)

Examination of the child in this situation is often performed concurrently, as rapid assessment is required. The principle of assessment in this “emergency” should principally address the need to establish an immediate safe airway. The degree of respiratory effort made by the child should be carefully observed, and signs such as an opisthotonic posture with severe recession prompt urgency. Pulse oximetry can be very useful in this situation but not relied upon, as decompensation can be rapid with reduced oxygen saturations being a late sign; in particular, if the child is breathing oxygen-enriched mixtures, severe hypercapnia can be masked. Often a child that is quietening in terms of their respiratory effort could be tiring and deteriorating rather than improving.

General assessment of signs of toxicity should also be made and these include measures of temperature, heart rate, and capillary refill. These signs can be determined by inspection of the patient alone with minimal contact. In an emergent airway, a more probing examination can lead to a rapid deterioration in symptoms and this should be avoided in an uncontrolled environment.

Attempts should be made to further evaluate such a child in a relatively more controlled theatre environment with a senior anesthetist and ear-nose-throat (ENT) surgeon present to assess and secure the airway as deemed appropriate. Several measures can be employed to manage an emergent airway that can lead to adequate control of the symptoms or at least to provide a holding measure whilst deploying the appropriate teams to manage the situation definitively. These include oxygen, nebulized adrenaline, Heliox, and steroids. If an infective etiology is suspected, a diagnostic MLB may not be necessary and, in fact, is often contraindicated in severe cases, such as acute epiglottitis.

The aim should be to stabilize the airway with either medical treatment that can include oxygenation, steroids, and antibiotics, or to secure the airway with intubation, often by the anesthetists with an ENT surgeon merely on standby in case of difficulty. Techniques for a difficult intubation include the use of the ventilating bronchoscope or intubation with an ET tube placed over a 2.7 mm Hopkins rod. These techniques are perhaps used less often by ENT surgeons due to the advances in airway adjuncts for our anesthetic colleagues. Equipment, such as video glidascopes, can improve the grade of view at laryngoscopy facilitating intubation. Fiberoptic intubation is also more commonplace but very difficult in the neonate.

Again, if intubation is not possible, the option of a surgical airway must be considered. The situation is still controlled if ventilation can still be achieved by either the bag and mask technique or a laryngeal mask airway (LMA). An NPA should be considered if the level of obstruction is at the nasal or oropharyngeal level. Similarly, distal disease may require positive airway pressure support.

## Extubation Difficulties/Failed Extubation

Once successful intubation has been achieved, it is hoped that a child can be successfully extubated with a view to further elective treatment or investigation as necessary. This is certainly the situation in cases of infective etiologies. However, those with underlying structural abnormalities represent a far more challenging situation and may require more immediate management as often intubation can lead to an irritation and worsening of the structural component. In fact, there are an increasing number of cases with difficulties in extubation, and this correlates with the number of premature infants with prolonged periods of intubation and ventilation.

Unfortunately, difficulty with extubation often leads to cases of multiple reintubations that can lead to further airway trauma, particularly to the very fragile neonatal subglottic mucosa.[67] Successful extubation relies upon optimal respiratory function, including a patent airway and sufficient respiratory drive and neuromuscular function. Therefore, in the very premature, the preferential management may require the neonate to remain ventilated for a prolonged period allowing lung function to improve. A period of expectant intubation can also minimize the problems that occur with repeated attempts at intubation following failed extubation. This period of “laryngeal rest” is often overlooked as a management option. In these cases, when extubation is finally planned, a 24- to 48-hour period of corticosteroid cover and aggressive management of gastro esophageal/laryngopharyngeal reflux is beneficial prior to extubation.

If there is a failed attempt at extubation, it is important to determine the symptoms and signs leading up to reintubation. Any accounts of stridor should suggest the likelihood of airway pathology although it may not be necessary to investigate this immediately if successful extubation can be achieved with the more conservative measures described above. However, if there is a recurrent problem, MLB should be performed to diagnose and plan the management of any underlying structural airway pathologies. For example, seal flipper granulations or subglottic cysts can be identified and removed to relieve any airway obstruction (Fig. 18.11). The caliber of the subglottis can also be assessed, and most importantly an early and evolving sub glottis stenosis can be treated (Fig. 18.12). If there are continued difficulties with failed extubation relating to ventilation issues or continued and significant airway pathology, a tracheostomy may be required in this period. If a tracheostomy is performed, it is important to monitor these cases so that any changes in the clinical situation can be monitored and the option of decannulation entertained.

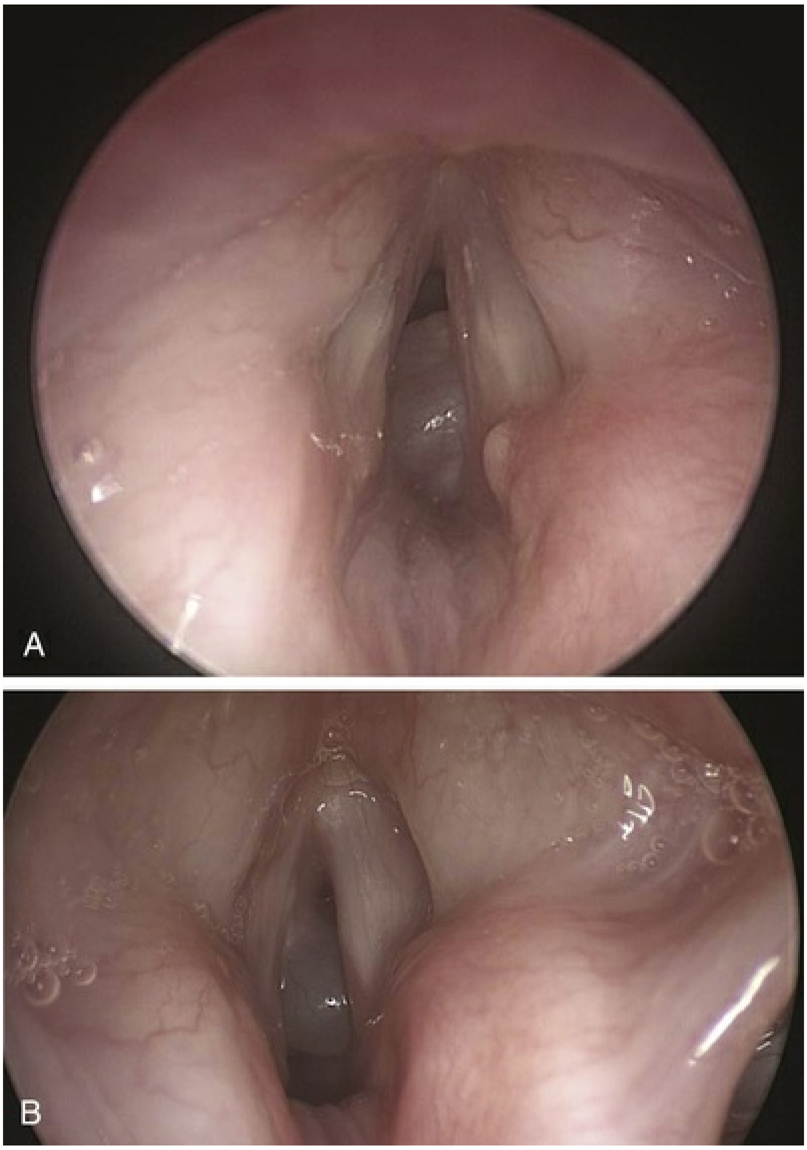

**FIG. 18.11** (A and B) Two examples of sublottic cysts secondary to intubation.

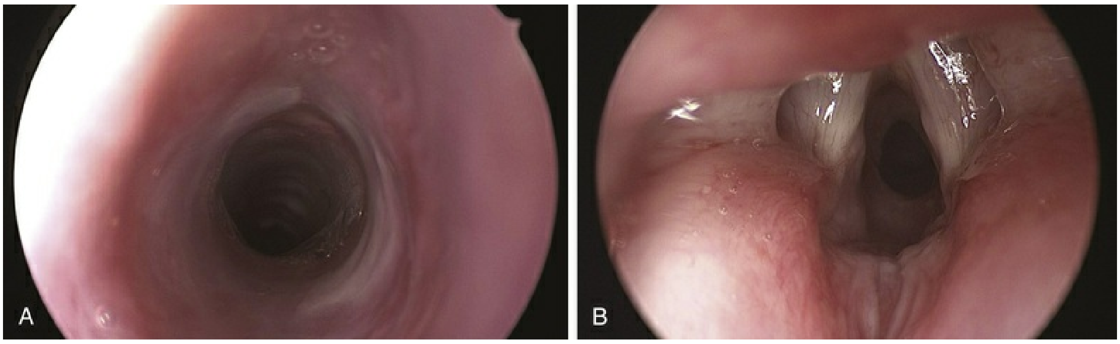

**FIG. 18.12** Intubation injury (A) removal of the endotracheal tube at microlaryngobronchoscopy reveals blanching of the subglottic mucosa. (B)

Damage to this fragile area subsequently leads to an acquired subglottic stenosis.

# Congenital Abnormalities of the Larynx

## Laryngomalacia

Laryngomalacia is a dynamic condition and is the most common cause of stridor in infants (Fig. 18.13). It occurs due to collapse of the relatively immature cartilaginous supraglottic structures, which has been postulated due to an incoordination of the laryngeal muscles due to neuromuscular immaturity. This leads to a mistiming of laryngeal movements and tends to cause indrawing and lengthening of the supraglottic structures. However, laryngomalacia may just be a structural variation.[68,69]

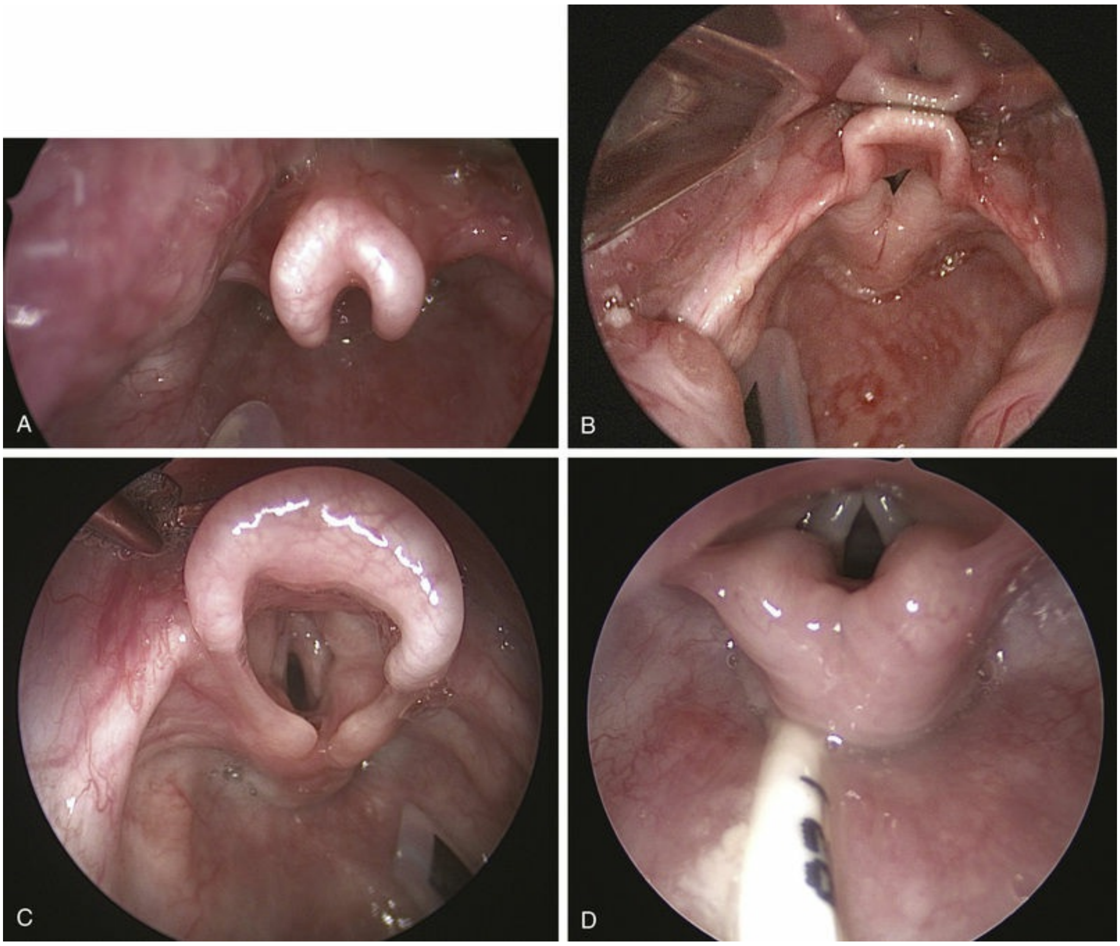

**FIG. 18.13** Appearances of laryngomalacia at microlaryngobronchoscopy. (A) Typical omega-shaped epiglottis. (B) Posterior view of collapsing laryngeal inlet. (C) Shortened aryepiglottic folds. (D) prominent arytenoid cartilages.

This functional collapse can be related to specific structural features:

1. The aryepiglottic folds are short and vertical, curling the epiglottis into an omega shape.
2. Prominent cuneiform and corniculate cartilages lie over the arytenoid cartilages, which prolapse into the airway.
3. A loose, redundant mucosal covering of the aryepiglottic fold prolapses into the airway.

There is a high concomitant incidence of gastroesophageal reflux in infants with laryngomalacia, presumably because of the more negative intrathoracic pressures necessary to overcome inspiratory obstruction.[70] Conversely, children with significant reflux may also exhibit pathological changes similar to laryngomalacia, especially enlargement and swelling of the arytenoid cartilages.

## Presentation

Laryngomalacia is most often managed without involvement of ENT surgeons in its mildest form with infants presenting to the primary care physician or pediatrician with stridor, but are otherwise well. The stridor is often not present at birth, but occurs during the first few weeks of life as it is postulated that inspiratory flow rates may not be adequate initially to generate airway noise. Symptoms are rarely present beyond the age of 2 years.

The prolapse of supraglottic structures produces an inspiratory stridor that is most evident when the infant is supine, or during feeding or crying; also, it has a characteristically high-pitched nature. Severe cases present with failure to thrive with infants falling off the growth centiles. Some children with laryngomalacia can have obstructive sleep apnea (OSA) associated with the condition and may require a detailed sleep history.

In most cases, diagnosis can be made on clinical grounds alone. As this is a dynamic condition, awake FNE can confirm the diagnosis. Cases that are moderate to severe or those with atypical features in the history may require MLB to rule out synchronous airway lesions and/or provide surgical therapeutic intervention. A sleep study may be indicated in those cases with a strong history of OSA.

Often the management is conservative with observation and reassurance until the symptoms subside with age. Serial plotting on a growth chart can be a useful tool in assessing satisfactory progress. Infants with reflux can be trialed on antireflux treatments. Surgical intervention, most commonly an aryepiglottoplasty/supraglottoplasty, is usually only required if there is concern about failure to thrive, or severe respiratory compromise/cyanotic spells, or, in cases of an atypical history and an unclear diagnosis.[71] There are serious potential complications of excessive removal of the supraglottic tissues including stenosis and aspiration. To avoid this, the surgery should be as limited as possible. However, surgery is very successful in controlling severe airway obstruction, but less so if there is concomitant neurological etiology; for example, cerebral palsy. Feeding problems often improve but still may be significant in a minority of patients.[72] Long-term consequences of severe laryngomalacia include exercise-induced laryngeal obstruction,[73] which may be diagnosed during direct laryngoscopy on exercise.[74,75]

## Laryngeal Atresia and Webs

The larynx develops from the endodermal lining of the cranial end of the laryngotracheal tube and from the surrounding mesenchyme derived from the fourth and sixth pairs of branchial arches. The epithelium proliferates rapidly, and this leads to an occlusion of the laryngeal lumen, which recannalizes by the tenth week of gestation. Failure to reestablish a complete lumen leads either to a laryngeal web or, in extreme cases, to complete atresia.

### Laryngeal Atresia

Laryngeal atresia was traditionally said to be incompatible with life, but with the advent of prenatal diagnosis there is the possibility of planned immediate airway treatment. This type of anomaly and similar gross abnormalities (e.g., laryngeal cysts) have been given the label of *congenital high airway obstruction syndrome (CHAOS).*[76] CHAOS is characterized by ultrasound findings of large echo genic lungs, a dilated airway distal to the obstruction, inverted diaphragms, and massive ascites. The early prenatal diagnosis provides two possible choices for airway intervention as follows:

1. *Ex utero intrapartum treatment (EXIT).* The principle of this management is to allow the infant's oxygenation to be maintained by the uteroplacental circulation for as long as possible. This can be prolonged by anesthetic treatment to produce uterine relaxation, though this relaxation must be reversed just before the cord is clamped to prevent uterine atony and excessive maternal bleeding. The hysterotomy is ultrasound-controlled to prevent damage to the placenta. Limited exposure of the fetus also helps in maintaining the uterine volume and fetal temperature.[77]

2. *Fetal Intervention.* It has proved technically possible to introduce a tracheostomy while still *in utero* (above)

## Laryngeal Webs

Laryngeal webs are a rare congenital anomaly (Fig. 18.14). They result from a failure of recanalization of the laryngotracheal tube during the third month of gestation and similarly can result in varying degrees of laryngeal webs. The most common site at which these develop is the anterior commissure, although webbing can be present in the posterior interarytenoid area, subglottic, or supraglottic regions. Key diagnostic points are to delineate any subglottic disease as well as any underlying congenital diagnosis, such as velocardiofacial syndrome (chromosome 22q11.2 deletion[78]).

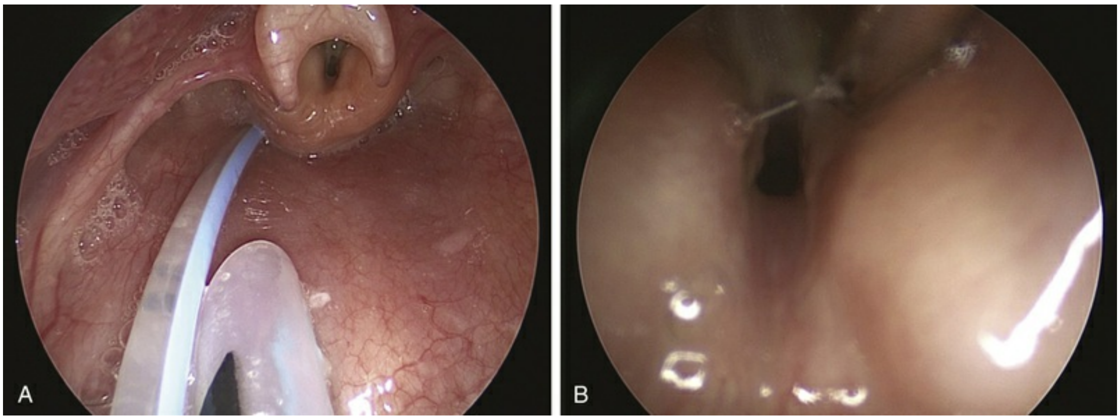

**FIG. 18.14** Laryngeal web seen at microlaryngobronchoscopy before (A) and after (B) treatment.

Cohen's classification system subdivides laryngeal webs into four types:

Type I: An anterior web involving 35% of the glottis or less. The vocal cords are visible through these thin webs.
Type II: An anterior web involving 35%–50% of the glottis, which may be thin or thick, with extension into the subglottis. The vocal cords are usually visible within the web.

Type III: An anterior web involving 50%–70% of the glottis, typically with a thick anterior portion and extension into the subglottis.

Type IV: 75%–90% of the glottis is involved by a uniformly thick web, which extends into the subglottic larynx. The individual vocal cords are not identifiable and may be fused together. There may be an associated abnormality of the anterior cricoid cartilage.

As anterior laryngeal involvement is the most common site, hoarseness is the most common presentation. This is certainly most likely with a thin anterior laryngeal web although a thicker lesion can result in aphonia. If the web is extensive and involves the subglottis, respiratory compromise may be evident (Fig. 18.15). The rarer posterior inter arytenoid webs can present with stridor secondary to the inability to abduct the vocal cords. Flexible nasoendoscopy can diagnose a laryngeal web but on its own is insufficient to evaluate the extent of the lesion or plan any treatment. Formal endoscopic evaluation by way of an MLB allows for the character and true extent of the lesion to be determined.

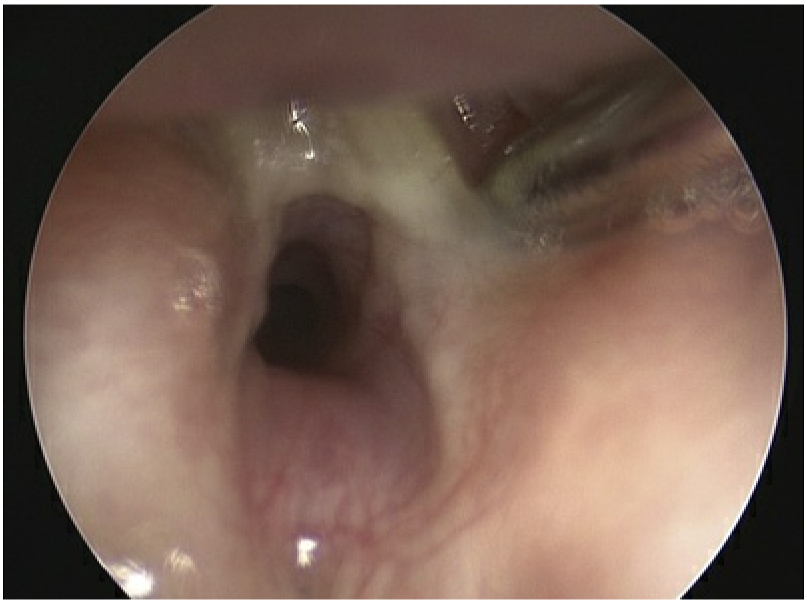

**FIG. 18.15** Microlaryngobronchoscopy picture of an anterior glottic web and associated grade 3 subglottic stenosis.

The management of a laryngeal web may simply be conservative with voice therapy support. Much of the concern regarding surgery relates to the possibility of web reformation and resultant scarring. The rare, thin anterior laryngeal webs may be endoscopically divided and dilated to good effect. More complex, thicker, or larger webs may require an endoscopic or an open approach. Endoscopic approaches involve wedge resection, suturing of the cut edges, placement of stents, mitomycin C topical application, or local flap reconstructions. Open approaches require laryngofissure and anterior cartilage graft placement. In most cases of complex webbing, revision procedures are commonplace and a tracheostomy is inevitable.[79]

## Laryngeal Cleft
